Introduction

Forward and reverse genetics have provided a wealth of information about the organization and function of biological systems. For decades, genome modification has relied on transgenesis, spontaneous gene replacement by homologous recombination (HR), and chemically induced or spontaneous generation of mutations. Although these approaches greatly contribute to advancing our knowledge of biological systems, they have some limitations. For example, spontaneous gene replacement and chemically induced mutations occur at random, and, in some cases, their frequency of occurrence is not sufficient to conduct forward genetic studies in a timely manner. Transgenesis requires the generation of large and complex DNA constructs, and their integration within a genome occurs at random, which often affects transgene expression. Moreover, transgenesis cannot be used to modify a specific location within a genome. Although gene replacement by HR is more precise than transgenesis and allows the modification of endogenous genes, HR is an infrequent event in cells. Consequently, the process requires the generation of large and complex DNA constructs with sequence homology to the target region and selectable markers to facilitate clone identification through positive and negative selections. Further, this technique is amenable to only a subset of cells in which HR is effective and in model organisms for which stem cells are available. The process is not always reliable and several rounds of blastocyst injections and transfer of blastocysts are required to generate mice that can transmit the mutant allele to their offspring.

Early studies in yeast and mammalian cells demonstrated that insertion of a DNA double-strand break (DSB) at a specific locus in a genome increases the frequency of gene replacement at that locus by several orders of magnitude compared with spontaneous gene replacement (Choulika et al., 1995; Cohen-Tannoudji et al., 1998; Donoho et al., 1998; Smih et al., 1995). Building upon these findings, scientists have developed targetable nucleases for genome engineering. These enzymes can introduce DNA DSBs within genomes with good accuracy.

Meganucleases, the first generation of targetable nucleases, were mainly used for proof-of-concept studies on HR in eukaryotic cells (Choulika et al., 1995; Cohen-Tannoudji et al., 1998; Donoho et al., 1998; Smih et al., 1995). Meganucleases recognize and cleave particularly long DNA sequences, which gives them an exquisite degree of specificity. However, the long DNA sequences recognized by meganucleases are practically absent from genomes of most species, thus impeding the use of these enzymes as a genome-editing tool.

In search of a more versatile genome-editing tool, scientists turned to zinc-finger nucleases (ZFNs) (Bibikova et al., 2003) and transcription activator-like effector (TALE) nucleases (TALENs) (Christian et al., 2010). These enzymes use naturally occurring DNA-binding domains fused to the non-specific endonuclease *FokI* (Li et al., 1992; Looney et al., 1989; Nwankwo and Wilson, 1987). Arrays of TALEs or zinc-finger proteins can recognize virtually any DNA sequence and can thus be programmed to target virtually any given DNA sequence. Although these protein domains provide the long-awaited versatility, programming and reprogramming of these enzymes to target other sites is difficult due to the repetitive nature of TALE DNA-binding domains and the complexity of ZFP engineering.

Adaptation of the microbial clustered regularly interspaced short palindromic repeat (CRISPR) and CRISPR-associated protein 9 (Cas9) immunity into a genome-editing tool finally provided the much-sought versatility and simplicity of programming while retaining efficacy and specificity (Hsu et al., 2013; Jinek et al., 2012; Mali et al., 2013b). In the CRISPR–Cas9 system, a large DNA endonuclease guided by a small RNA transcript recognizes and cleaves double-stranded DNA. Unlike ZFNs and TALENs that rely on protein–DNA interactions for target recognition, the CRISPR–Cas9 system uses conventional RNA–DNA base pairing. Hence, in contrast to the complete reengineering of nucleases required for ZFNs and TALENs reprogramming, the simple modification of the RNA sequence is sufficient to redirect the endonuclease Cas9.

In this article, I describe adaptation and implementation of the CRISPR–Cas9 technology for genome editing and regulation in mammalian systems. I also summarize the applications of CRISPR–Cas9 modalities in agriculture, biotechnology, biology, biomedical research, and medicine.

CRISPR–Cas9 Genome Editing

Class 2 Type II CRISPR–Cas9 Adaptive Immunity

Several CRISPR–Cas9 systems have been adapted for editing and regulation of genomes, most being derived from class 2 type II or type V bacterial adaptive immune systems (Makarova and Koonin, 2015). These systems function by incorporating DNA sequences from invading bacteriophages for their reuse by large DNA endonucleases as targeting devices to direct the selective degradation of invading DNA upon subsequent infections.

This article is a reprint of Stephane Pelletier, CRISPR–Cas9, *Reference Module in Life Sciences*, Elsevier, 2017.

Fig. 1 Class 2 type II CRISPR–Cas9 from *Streptococcus pyogenes* and its adaptation as a genome-editing tool. (a) The type II CRISPR–Cas9 operon from *S. pyogenes* contains 4 genes (gray arrows), a CRISPR array containing repeat elements (gray rectangles) regularly interspaced with spacer elements (colored circles), and sequences encoding the transactivating crRNA transcript (tracrRNA, blue arrow). (b) Schematic representation of type II CRISPR–SpCas9 adaptive immunity. CRISPR–Cas9 immunity is divided into 3 stages: adaptation (stage I), expression and maturation (stage II), and interference (stage III). In the adaptation stage, Cas1, Cas2, and Csn2 coordinate the excision and integration of small DNA fragments from invading DNA molecules (bacteriophages or plasmids) into the CRISPR array. In the expression stage, the CRISPR array, tracrRNA, and Cas9 are expressed, form a ribonucleoprotein complex, and precrRNA is further processed into mature crRNAs by RNase III. In the interference stage, the mature tripartite ribonucleoprotein complex targets invading RNA molecules for degradation upon subsequent infection. (c) Adaptation of type II CRISPR–SpCas9 for genome editing. Some modifications have been made to SpCas9 and RNA transcripts for use as genome-editing tools. First, tracrRNA and crRNA have been linked by an artificial loop to form the single-guide RNA (sgRNA) molecule. Second, SpCas9 cDNA has been optimized for mammalian codon usage. Third, a nuclear localization signal has been added to SpCas9 to facilitate its translocation to the nucleus of eukaryotic cells. Cloud-like gray shape, Cas9; black, genomic DNA; orange crRNA (left) or sgRNA (right); blue, tracrRNA; green, PAM sequence; black arrowhead, RuvC-like endonuclease cleavage site; and blue arrowhead, HNH cleavage site. (d) Sequence of the sgRNA transcript used by SpCas9. Nucleotides shown in red, orange, and blue are complementary and forms hairpins. N represents any nucleotide. The 5'-most end of the sgRNA, represented by Ns, corresponds to the guide sequence.

Like most genetic regulatory systems found in bacteria, CRISPR–Cas9 systems are organized in operons (Makarova and Koonin, 2015). The type II CRISPR–Cas9 operon from *Streptococcus pyogenes*, which is the prototypical CRISPR–Cas9 system discussed in this article, comprises 4 genes *Cas1*, *Cas2*, *Csn2*, and *Cas9* (or *SpCas9* for *S. pyogenes* *Cas9*); a CRISPR array; and DNA sequences encoding a short RNA transcript called trans-activating CRISPR RNA (tracrRNA) (Fig. 1(a)). *Cas1*, *Cas2*, and *Csn2* are involved in the adaptation stage (stage I), whereas *Cas9*, tracrRNA, and the CRISPR array are mainly involved in expression and maturation and interference stages (stages II and III, respectively) of adaptive immunity (Fig. 1(b)). In the adaptation stage, *Cas1*, *Cas2*, and *Csn2* regulate the incorporation of small foreign DNA fragments derived from an invading bacteriophage or plasmid into the genome of host cells. These fragments, called spacers, are incorporated into the CRISPR array, which is intercalated by short repeat elements (Amitai and Sorek, 2016). In the expression stage, both tracrRNA and pre-crRNA are expressed and pre-crRNA is processed to mature crRNA by the joint action of *Cas9*, tracrRNA, and RNase III (a ribonuclease that processes double-stranded RNA molecules) (Deltcheva et al., 2011). At this stage, *Cas9* is associated with both RNA molecules, and the tripartite ribonucleoprotein complex can recognize and degrade invading DNA molecules.

Target specificity for CRISPR–Cas9 adaptive immunity is provided by the mature crRNA, more specifically via the 5′-most 20-nucleotide (nt) segment of the RNA transcript (Jinek et al., 2012). This sequence forms a RNA–DNA hybrid with its cognate genomic DNA sequence, called protospacer element, according to Watson–Crick base-pairing rules. The 3′ end of the crRNA contains the repeat element of the CRISPR array and associates with the 5′-most end segment of the tracrRNA molecule. The RNA–RNA duplex binds *Cas9* via the scaffolding region of tracrRNA.

Cas9 possesses 2 distinct endonuclease domains: (1) a RuvC-like domain, which cleaves the DNA strand displaced by formation of the RNA–DNA hybrid, and (2) an HNH domain, which cleaves the annealed strand. Cleavage of target DNA also requires the presence of a specific DNA sequence located at the 3′ end of the protospacer element. This sequence, called protospacer adjacent motif (PAM), often differs among species. For example, *Cas9* from *S. pyogenes* or *S. mutans* requires the trinucleotide 5′-NGG-3′ (where N represents any nucleotide) for maximal activity, whereas *Cas9* from *C. jejuni* requires the heptanucleotide sequence 5′-NNNNACA-3′. Table 1 summarizes PAM requirements for *Cas9* endonucleases from different species. *Cas9* from different species also differs in size and crRNA/tracrRNA-binding properties and cleaves DNA at various locations within the protospacer element.

Adaptation of CRISPR–Cas9 for Genome Editing

For the purpose of genome editing, the CRISPR–*SpCas9* system has been simplified and requires only 2 (and not 3) components (Fig. 1(c) and (d)) (Jinek et al., 2012). The tracrRNA and crRNA have been fused to form a 96-nt single-guide RNA (sgRNA) molecule (Fig. 1(d)). The first 20 nt correspond to the spacer element, followed by 30 nt that correspond to the direct strand of the repeat element and the 5′ end of tracrRNA, which is complementary to the repeat element, linked by a 4-nt artificial hairpin. The last 46 nt correspond to the scaffolding portion of tracrRNA.

Modifications have also been made to *SpCas9* (Fig. 1(c)). It has been optimized for codon usage in mammalian cells and to include a nuclear localization signal (NLS) (Hsu et al., 2013; Mali et al., 2013b). The NLS of *Cas9* facilitates transport of the endonuclease to the nucleus of the target cell. In this system, simple modification of the first 20 nt of the sgRNA is sufficient to reprogram *Cas9* to target another locus within any given genome (Jinek et al., 2012).

Efficacy and Specificity

The efficacy of CRISPR–Cas9 systems to cleave DNA is equal or superior to that of other gene editing platforms. However, unlike ZFNs and TALENs that can target virtually any location within a genome, CRISPR–Cas9 systems require the presence of PAM

sequences, which are specific nucleotide sequences at the 3' end of target sequences. Although this was originally viewed as a major limitation for the use of CRISPR-Cas9 systems for genome editing, it was later shown *SpCas9* PAM sequences (5'NGG-3') occur at every 10 nt in the mouse genome and theoretically at every 8 nt in other genomes (including the human genome), supporting that *SpCas9* can target virtually any location within genomes (Pelletier et al., 2015). Moreover, several other CRISPR-Cas9 systems, including engineered ones, have been adapted for genome editing (Table 1). These CRISPR-Cas9 systems have distinct PAM sequence requirements, which expand their targeting capabilities. In addition, sequence composition of the sgRNA can also influence Cas9 activity. Nucleotide composition, in particular the nature of the 3'-most nucleotide of the guide sequence, can have different effects on the cleavage efficacy of Cas9: the presence of a guanine can increase Cas9 activity whereas that of a thymidine can have the opposite effect (Chari et al., 2015).

The most important limitation to using CRISPR-Cas9 systems as genome-editing tools is that they can target sites other than those for which they were designed. Studies show that *SpCas9* can tolerate the presence of several nucleotide mismatches between the sgRNA and its genomic target (Hsu et al., 2013; Jinek et al., 2012). Although bioinformatics tools have been developed to design and predict sgRNA on- and off-target sites, it is still difficult to identify all potential target sites of an sgRNA by using *in silico* models. To minimize off-targeting, we and others have developed single-guide selection procedures based on the singularity of guide sequences within a genome. Our procedure, which has been detailed previously (Pelletier et al., 2015), uses the algorithm developed by the Center for Genome Engineering, Institute for Basic Science, Korea (see Relevant Websites section). Our strategy provides a comprehensive list of all potential off-target sites associated with all possible guides for a given locus, which facilitates the selection. Approximately 70 mouse lines and several mouse and human cell lines have been designed and generated under my guidance by using this procedure (Gingras et al., 2017; Ippagunta et al., 2016; Karki et al., 2016; Lin et al., 2016; Man et al., 2017; Martinez et al., 2015; Pelletier et al., 2015; Van de Velde et al., 2016). In most cases, we have been able to avoid off-target cleavage.

In addition to the careful selection of guide sequences, several other approaches have been developed to limit Cas9 activity at undesired sites. These include the use of paired DNA nickases (Fig. 2(a)), shorter sgRNA molecules, inducible Cas9 systems, and self-inactivating Cas9 plasmids or engineered Cas9 with increased specificity (Fu et al., 2014; Guilinger et al., 2014; Mali et al., 2013a; Moore et al., 2015; Nihongaki et al., 2015a; Nihongaki et al., 2015b; Ran et al., 2015; Slaymaker et al., 2016). Paired nickases (*SpCas9*-D10A), in which the HNH domain has been inactivated, or the d*SpCas9*-FokI fusion, which employs a catalytically inactive Cas9 fused to the non-specific endonuclease FokI, which function as obligate dimer (Fig. 2(b)), provide increased specificity by targeting 2 juxtaposed genomic sequences oriented in opposite directions. The chances of having the same 2 target sequences anywhere else in the genome are quasi inexistent, thereby reducing the risk of off-target cleavage. Shorter sgRNAs are thought to increase target specificity by reducing the affinity of sgRNAs for their cognate on- and off-target sites. Shortening the duration of Cas9 activity by using inducible systems or self-inactivating plasmids or through direct delivery of DNA by plasmid-free systems (e.g., RNA transcript or RNA-protein complexes; see below) can reduce off-target activity. Cas9 systems with improved specificity have also been engineered by substituting some amino acids that have nonspecific interactions with the backbone of the DNA target.

CRISPR-Cas9 Plasmids and Delivery Methods

Several plasmids encoding various components of CRISPR-Cas9 have been developed for genome editing and other applications. These include conventional and viral vectors encoding both Cas9, generally under the control of strong promoters such as CBh (a hybrid form of the chicken b-actin [CBA] promoter), or sgRNA under the control of the U6 promoter. These vectors also generally express selection markers in the form of genes conferring resistance to chemical drugs or fused with fluorescent proteins. CRISPR reagents can also be produced *in vitro*, without the need of a vector, for physical delivery of reagents. Cas9, in the form of mRNA transcripts or protein, and sgRNA can be produced *in vitro* and delivered by microinjection and other approaches (see below). Plasmids encoding individual components of these systems have been developed, and some are available at Addgene (see Relevant Websites section).

Viral or non-viral methods can be used to deliver CRISPR-Cas9 reagents. Viral delivery systems use viral vectors to package various components of the genome-editing system. Several viral vector platforms have been used to deliver CRISPR-Cas9 components, such as adenoviruses, adeno-associated viruses, retroviruses (in particular lentiviruses and integrase-deficient lentiviruses), and baculoviruses. In contrast, non-viral delivery systems use physical and/or chemical methods to deliver components. Non-viral delivery systems include electroporation, chemical transfection, mechanical stress transduction, or microinjection of ribonucleoprotein particles or plasmids encoding various components of systems. Cell-penetrating peptides genetically or chemically fused to Cas9 are also used to deliver Cas9 via endocytic pathways. Both viral and non-viral delivery methods have been successfully used *in vivo*, *ex vivo*, and *in vitro*.

Basic Principles of Genome Editing Using CRISPR-Cas9 Technology

It has long been recognized that insertion of DNA DSBs increases the gene replacement frequency in mammalian cells (Choulika et al., 1995; Cohen-Tannoudji et al., 1998; Donoho et al., 1998; Smih et al., 1995). Insertion of DNA DSBs triggers DNA repair mechanisms within cells, of which HR and nonhomologous end joining (NHEJ) are the most common (Fig. 3) (Chapman et al., 2012). DNA repair via the NHEJ pathway often results in the insertion or deletion of relatively small DNA segments or nucleotide substitutions. Repair via HR results in proper rearrangement of the DSB and uses the sister chromatid as the repair template. These pathways compete with each other within cells, and in most cells NHEJ is the more prevalent repair pathway.

Fig. 2 CRISPR–*SpCas9* modalities for genome editing. (a) Genome editing using a paired *SpCas9*–D10A. The D10A mutation inhibits the HNH endonuclease activity of *SpCas9*. A paired *SpCas9*–D10A recognizing the opposite strand of a locus can be used to introduce scattered DNA double-strand breaks (DSBs). The use of paired nickases can reduce off-target cleavage. (b) Genome editing using a pair of catalytically inactive Cas9 fused to the endonuclease *FokI*. *FokI* functions as an obligate dimer. Targeting d*SpCas9*–*FokI* enzymes on opposite strands (head to head) introduces scattered DNA DSBs at the locus, which can serve as a substrate for DNA repair pathways. (c) Base editing using the RuvC-like-deficient but HNH-competent APOBEC–XTEN–RuvC–*SpCas9*–UGI fusion. APOBEC–XTEN catalyzes the deamination of a uracil to a cytosine. The substitution is stabilized by the presence of a UGI. Genome editing employing base editing does not require the insertion of DNA DSBs. (d) Genome editing using inducible split *SpCas9*. A split Cas9 fused to the photoactivatable system Magnet (pMag and nMag). Blue light triggers dimerization of the split Cas9. A similar system in which FK506-binding protein 12 (FKBP) and FKBP–rapamycin binding (FRB) domains have been fused to split Cas9 has also been developed. In this case, dimerization is triggered by rapamycin. Light-gray cloud-like shape, *SpCas9*; orange traces, sgRNAs; green lines, PAM sequences; dark gray shapes, functional entities (*FokI*, a non-specific endonuclease; UGI, uracil glycosylase inhibitor; APOBEC–XTEN, cytosine deaminase); black arrowhead, RuvC-like endonuclease cleavage site; blue arrowhead, HNH endonuclease domain; black lines, genomic DNA locus; pMag, positive magnet; nMag, negative magnet.

Specific mutations within a genome are usually introduced by co-administration of exogenous DNA templates containing the desired mutations. This process, generally referred to as homology-directed repair (HDR), uses single-stranded DNA (ssDNA) or double-stranded DNA molecules (linear or circular) as a template for repair. Introducing mutations by using double-stranded DNA templates likely uses the HR pathway (Chapman et al., 2012), and recent evidence suggests that ssDNA editing may involve the Fanconi anemia DNA repair pathway (see Relevant Websites section), which involves components of the HR pathway, nucleotide excision repair pathway, and mutagenic translesion synthesis (Moldovan and D’Andrea, 2009).

Genome-Editing Strategies

Virtually any type of genomic alteration can be introduced through CRISPR–Cas9 technology. A gene can be inactivated by inserting a single DNA break within a critical exon. Repair of the break by the NHEJ pathway may result in insertion or deletion of

Fig. 3 DNA repair pathways engaged by targetable nucleases. Homologous recombination (HR) and nonhomologous end joining (NHEJ) are the most common DNA DSB repair pathways. Resolution of DNA DSBs by the error-prone NHEJ pathway usually results in insertion or deletion of genetic material caused by misalignment of resected strands during the repair process. Resolution of the DSB by HR uses the sister chromatid as a repair template and is thought to be error free. Specific mutations or large DNA elements can be inserted by co-administration of a homology directed repair (HDR) template. HDR templates are usually single-stranded (ss) or double-stranded (ds) DNA molecules that have sequence homology to the target locus. Repair pathways involved in this process depend on the type of repair templates used. ssDNA repair templates may be used by the Fanconi anemia repair pathway, whereas dsDNA templates may be used by the HR pathway.

nucleotides, which causes a nonsense or frameshift mutation, leading to the formation of a premature stop codon (Fig. 4(a)). mRNA transcripts with premature stop codons are often recognized as defective and are degraded via the nonsense mRNA decay pathway (Popp and Maquat, 2016). A shortcoming of this strategy is that break repair by the NHEJ pathway can also result in the insertion of missense or silent mutations that do not disrupt gene function or potentially provide adverse properties to the encoded protein. This limitation can be resolved by co-administering a repair template that contains one or more stop codons in one or all reading frames (Martinez et al., 2015).

Another strategy for gene inactivation is partial or complete removal of a gene, assuming that the targeted region does not contain other genes such as microRNAs or transfer RNAs (tRNAs). Large chromosomal deletions can be achieved by introducing 2 DNA DSBs in the coding or noncoding regions of a gene (Fig. 4(b)). Break repair can result in complete removal of a gene located between the 2 breaks. Importantly, introduction of 2 DNA DSBs can also result in inversion of the intervening region, which might have unpredictable consequences (Fig. 4(b)). This strategy has been used to not only inactivate genes in model organisms and cell lines (Gingras et al., 2017; Karki et al., 2016; Man et al., 2017; Van de Velde et al., 2016) but also remove regulatory elements termed microRNAs, including those located in introns of genes, tRNAs, long noncoding RNAs, and gene clusters of the same family (Fig. 4(c)) (Van de Velde et al., 2016). This strategy can also be used to inactivate splice variants of a gene without affecting other isoforms. We are currently using this strategy to remove specific domain(s) of proteins in vivo. HDR templates are co-administered with the RNA-guided nuclease to promote specific recombination events.

Conditional alleles, which allow the spatial and/or temporal removal of genes, can also be generated by introducing 2 DNA DSBs and co-administering DNA repair templates containing recombinase recognition sites (e.g., *LoxP*, *FRT*, *Lox511*) flanked by DNA sequences homologous to the target site (Fig. 4(b)). In addition to inserting *loxP* sites independently, other methods to insert *loxP* sites include the insertion of 2 DSBs flanking a single critical exon and repair of the break using a large DNA molecule (single stranded or double stranded) containing the targeted exon flanked by 2 *loxP* sites and sequences homologous to the target site (Ippagunta et al., 2016).

Genes can also be conditionally inactivated by regulated expression of Cas9 by either using plasmids encoding Cas9 under the control of an inducible promoter or by expression of a photoactivatable (or chemically induced) split Cas9 or nuclease-deficient Cas9 (dCas9) fused to transcriptional activators or repressors (Fig. 2(d)). Chromosomal translocations, a frequent rearrangement in cancer cells, can be generated by inserting 2 DNA DSBs located on 2 distinct chromosomes. Chromosomal translocations generated using this strategy can be facilitated by co-administering an HDR template with sequence homology to the targeted chromosomes (Fig. 4(d)). Such translocations can also be made conditional by inserting recombinase recognition sites at break sites (Fig. 4(d)).

In addition to inactivating genes, RNA-guided nucleases also facilitate the study of specific or disease-associated mutations in the context of the endogenous gene or the whole organism. This is of the utmost importance, especially for understanding disease mechanisms and performing structure–function studies. Overexpression of mutant proteins may have nonspecific and/or

Fig. 4 Genome-editing strategies using CRISPR-Cas9. (a) A single DNA DSB can be inserted to generate various alleles. Null alleles can be generated by inserting a single DNA DSB. Break repair via the NHEJ pathway can result in insertion of a nonsense or frameshift mutation, leading to the formation of a premature STOP codon (red) and mRNA decay. Single DNA DSBs can also be inserted to introduce a STOP codon or other desired mutations (green) or insert large DNA elements such as DNA sequences encoding epitope tags, fluorescent proteins, or other functional entities. (b) Two DNA DSBs can be inserted within a gene to inactivate genes or generate conditional alleles. Break repair via the NHEJ pathway often results in deletion of the region flanked by DNA DSBs. Inversion of the intervening region is also possible. Co-administration of HDR templates containing recombinase recognition sequences can be used to generate conditional alleles. (c) Two DNA DSBs can be inserted to delete entire chromosomal regions. Break repair via the NHEJ pathway can result in removal or inversion of an entire chromosomal section. (d) Two DNA DSBs can be inserted in 2 distinct chromosomes to promote chromosomal translocation, an aberration observed in cancer cells. LoxP sites or other recombinase recognition sequences can be co-administered to make the translocation conditional. Boxes, exons; lines, non-coding region of a gene (introns, 5' and 3' untranslated regions); red boxes, STOP codons; yellow boxes, frameshift mutations or indels; green boxes, designed mutations or inserted DNA elements; blue triangles, DNA recombinase recognition sequences; HDR pathway, homology-directed repair pathway (HR or FA); NHEJ, nonhomologous end joining.

deleterious effects on cellular processes that would normally not be present in the context of the endogenous gene or organism. Specific mutations can be introduced by inserting a DNA DSB and co-administering a repair template containing the desired mutation flanked by sequences homologous to the target region (Fig. 4(a)). This strategy has been used to introduce mutations in cell lines as well as in model organisms (Lin et al., 2016; Martinez et al., 2015; Pelletier et al., 2015; Wang et al., 2013; Yang et al., 2013).

In addition to facilitating the insertion of point mutations and recombinase recognition sites, CRISPR-Cas9 systems are used to introduce small or large DNA elements such as epitope tags, Lox-STOP-Lox cassettes, transcriptional response elements, and cDNAs encoding fluorescent proteins. These elements are introduced by inserting 1 or 2 DNA DSBs and co-administering a DNA repair template containing the element to be inserted flanked by sequences homologous to the target site (Fig. 4(a)) (Yang et al., 2013).

Small edits can also be introduced within genomes without introducing DNA DSBs (Komor et al., 2016). For example, base editing uses an endonuclease-defective mutant of Cas9, in which one of the nuclease domains, the RuvC-like domain, is inactivated and various enzymatic activities are fused to it (Fig. 2(c)). These enzymes include the cytidine deaminase APOBEC-XTEN (catalyzes the conversion of cytosine to uridine) and a uracil glycosylase inhibitor (UGI; prevents reversion of uracil to cytosine). Nicking of the unmodified strand by the HNH domain of Cas9 RuvC— stabilizes nucleotide conversion. Like other CRISPR-Cas9 systems, the modified Cas protein is targeted to specific genomic loci through the binding of an sgRNA.

Genome-Wide Screens

Single-guide RNA libraries have also been developed for genome-wide screens studies and are available at Addgene. These libraries contain several guide RNAs (gRNAs) targeting each gene of the fly, mouse, or human genome. Some libraries also include gRNAs that target microRNAs and long-coding RNAs. Most libraries enable genome-wide screens that require the use of next-generation sequencing to measure enrichment or depletion of specific gRNAs. These genome-wide screens thus require robust assays for monitoring enrichment or depletion, such as cell death and survival or proliferation. GE Healthcare has also developed libraries that do not impose such limitations on assay designs and are available as lentiviral particles delivered in 96-well-plate formats.

CRISPR-Cas9 Genetic Regulation

Gene Expression or Repression (CRISPR Activation and CRISPR Interference)

Although primarily developed for genome editing, CRISPR-Cas9 systems have also been designed to upregulate or downregulate gene expression without modifying the target cell's genome (Cheng et al., 2013; Gilbert et al., 2014; Qi et al., 2013). Gene expression is modulated by the fusion of transcriptional activators such as VP64 (Fig. 5(a)) or transcriptional repressors such as KRAB to a catalytically inactive but gRNA-competent Cas9 (dCas9) (Fig. 5(b)). Transcriptional activation or repression is achieved by targeting one or more dCas9 fusion proteins to a gene promoter. Differential regulation can be obtained by increasing or reducing the number of transcriptional regulators to a specific promoter. Genome-wide libraries for activation and repression are available at Addgene. Screens using these libraries also require next-generation sequencing and robust functional enrichment or depletion assays.

Modulation of Epigenetic Markings

Epigenetic markings occur on both DNA and DNA-binding proteins. These markings, such as DNA methylation; histone acetylation and methylation; and ADP ribosylation, ubiquitination, sumoylation, and phosphorylation can affect gene expression. Selective modulation of these DNA markings at specific sites in the genome can provide information about the functional relevance of these posttranslational modifications on gene regulation. Epigenetic markings can be modulated by fusing the DNA or DNA-binding protein marking enzymes to catalytically inactive but gRNA-competent Cas9 (Fig. 5(c)) (Vojta et al., 2016). In this way, these functional entities can be targeted to various regions in an sgRNA-dependent manner to any genomic location and enable site-directed DNA or histone modifications.

CRISPR-Cas9 Tracking Devices

In addition to modulating gene expression and editing genomes, CRISPR-SpCas9 has been repurposed as tracking device to visualize specific DNA loci or mRNA transcripts (Chen et al., 2013; Nelles et al., 2016). The chromosomal region is visualized using dCas9 fused to a fluorescent protein marker such as green fluorescent protein (GFP). The tiling of Cas9-GFP fusions using several sgRNA molecules targeting a specific region of a chromosome can then promote the accumulation or fluorescently tagged dCas9 to that locus (Fig. 5(d)). This strategy was first used to visualize telomeres in cultured cells (Chen et al., 2013).

A similar strategy has also been devised to visualize endogenous mRNA transcripts within cultured cells (Nelles et al., 2016). In this system, a catalytically inactive Cas9 is fused to a fluorescent protein. The modified Cas9 is targeted to specific RNA transcripts, using both a sgRNA with sequence complementary to the RNA transcript and an oligonucleotide called PAMer. This oligonucleotide also possesses sequence complementarity to the mRNA transcript as well as a decoy PAM sequence that is recognized by Cas9 (Fig. 5(e)).

Fig. 5 CRISPR–Cas9 for genome regulation. (a) Transcriptional activator. *SpCas9* has been converted into a transcriptional activator by fusion of a catalytically inactive *SpCas9* to transcriptional activators (TAs) such as VP16/VP64 or p65 activation domains. Tiling of these site-specific transcriptional devices on gene promoters can modulate gene expression. (b) Transcriptional repressor. *SpCas9* has been converted to site-specific transcriptional repressors by the fusion of a catalytically inactive *SpCas9* to transcriptional repressors (TRs) such as KRAB or SID. Tiling of these site-specific transcriptional repressors on genes promoters can be used to modulate repression. (c) DNA and DNA-binding protein modifying devices. *SpCas9* has been converted to locus-specific epigenetic marking enzymes. For example, the fusion of a catalytically inactive *SpCas9* to DNA methylases such as DNMT3A or histone deacetylases can promote site-specific epigenetic modifications. (d) Genomic DNA tracking devices have been generated by fusing a catalytically inactive *SpCas9* to fluorescent proteins such as mCherry or GFP. Tiling of these fusion proteins to a genomic locus can enable its visualization in real time. (e) Live imaging of the RNA transcript using a catalytically inactive *SpCas9* fused to a fluorescent protein such as GFP can enable the visualization of mRNA transcripts. In this system, a small oligonucleotide PAMer is co-administered with the sgRNA and *SpCas9*. The PAMer serves as molecular decoy by providing a PAM sequence to the DNA–RNA hybrid.

Orthogonality of CRISPR–Cas9 Platforms

As mentioned earlier, several CRISPR–Cas9 and CRISPR–Cpf1 systems have been adapted for genome editing and regulation, with each system having distinct PAM requirements and Cas9-binding properties. These orthogonal properties of CRISPR–Cas9 systems allow the use of one system in combination with another to perform distinct functions within a single cell. For example, using these systems, it is possible to induce the expression of a specific gene while simultaneously inactivating another (Esvelt et al., 2013).

Applications of CRISPR–Cas9 Systems

CRISPR–Cas9 systems have found applications in a broad range of disciplines such as agriculture, biotechnology, biomedical research, drug development, and medicine. In crops and livestock, the CRISPR–Cas9 platform has been used to increase

productivity or provide resistance to pathogens. In biomedical research, they have been used to identify gene function, study structure–function relationships, and rapidly and efficiently generate cellular or animal models of human diseases. The ease with which cellular and animal models are generated also accelerates target validation for drug development. In medicine, CRISPR–Cas9 technologies have been used to repair disease-causing mutations in model organisms. In the last 5 years, the platform has moved from proof-of-concept to clinical trials. In biotechnology, CRISPR–Cas9 platforms have been used to modify cells and microorganisms to produce more effective recombinant pharmaceuticals. Also, microbe or plant metabolism can be manipulated to increase the efficiency of biofuels production.

Concluding Remarks

We are currently redrawing the blueprint of life with the hope of finding cures to human diseases. Among all genome-editing tools, RNA-guided nucleases, in particular CRISPR–Cas9 technologies, are the most promising. Not only are these genome editing systems significantly contributing to our understanding of biology in general, they also hold great promise to curing many genetic disorders through gene function identification and modeling human diseases. As we move forward with the development of these incredibly powerful genome-editing tools, it is also important to develop ethical and regulatory guidelines for this technology to ensure their safe use.

Crystalline Cell Surface Layers (S-Layers)[☆]

Uwe B Sleytr, Andreas Breitwieser, and Dietmar Pum, University of Natural Resources and Life Sciences Vienna, Vienna, Austria

© 2019 Elsevier Inc. All rights reserved.

Introduction

The different cell wall structures observed in prokaryotic organisms, particularly the outermost envelope layers exposed to the environment, reflect evolutionary adaptations of the organisms to a broad spectrum of selection criteria. Crystalline cell surface layers (S-layers) are now recognized as common features of both bacteria and archaea.

Most of the presently known S-layers are composed of a single (glyco)protein species endowed with the ability to assemble into two-dimensional arrays on the supporting envelope layer. S-layers, as porous crystalline membranes completely covering the cell surface, can apparently provide the microorganisms with selective advantages by functioning as protective and anti-fouling coats, molecular sieves, molecule and ion traps, and as a structure involved in cell adhesion and surface recognition. In those archaea that possess an S-layer as exclusive envelope component outside the cytoplasmic membrane, the crystalline arrays act as a framework that determines and maintains cell shape and may also aid in cell division. In pathogenic organisms S-layers have been identified as virulence factors.

S-layers, as the most abundant of bacterial cellular proteins and thus on earth too, are important model systems for studies of structure, synthesis, assembly, and function of proteinaceous components, and evolutionary relationships within the prokaryotic world. S-layers also have considerable application potential in biotechnology, biomimetics, biomedicine, molecular nanotechnology, and synthetic biology (Table 1).

Location and Ultrastructure

Although considerable variation exists in the complexity and structure of bacterial cell walls, it is possible to classify cell envelope profiles into the following main groups on the basis of structure, biochemistry, and function (Fig. 1):

1. Cell envelopes formed exclusively of a crystalline S-layer composed of (glyco)protein subunits external to the cytoplasmic membrane (most halophilic, thermophilic and acidophilic, alkaliphilic, barophilic, and Gram-negative archaea (Fig. 1A). The inner part of the S-layer protein partially inserts into the hydrophobic domain of the cytoplasmic membrane or even penetrates it. Anchoring of the S-layer may also involve lipid modified glycoprotein subunits (Fig. 1B).
2. Gram-positive cell envelopes of bacteria with a rigid peptidoglycan-containing sacculus of variable thickness outside the cytoplasmic membrane (Fig. 1D), and Gram-positive cell envelopes of archaea with a rigid sacculus composed of pseudomurein or other polymers (Fig. 1C).
3. Gram-negative envelopes of bacteria with a thin peptidoglycan sacculus and an outer membrane (Fig. 1E).

Although not a universal feature as in archaea, crystalline arrays of (glyco)proteins have been detected as outermost envelope components in organisms of most major phylogenetic branches of Gram-positive and Gram-negative bacteria.

The most useful electron microscopy preparation procedure for detecting S-layers on intact cells is freeze-etching (Fig. 2).

S-layers completely cover the cell surface at all stages of cell growth and division in both archaea and bacteria. High-resolution electron microscopy and scanning force microscopy studies revealed that S-layer lattices can have oblique (p1, p2), square (p4), or hexagonal (p3, p6) lattice symmetry (Fig. 3) with a center-to-center spacing of the morphological units (composed of one, two, three, four, or six identical monomers) of approximately 5–35 nm. Among archaea, hexagonal lattices were shown to be predominant. S-layers are generally 5–25 nm thick and have a smooth outer and a more corrugated inner surface. Since S-layer lattices are monomolecular assemblies of identical subunits, they exhibit pores of identical size and morphology (Fig. 3). S-layers can display more than one type of pore. From high-resolution electron microscopy, scanning force microscopy, and permeability studies, pore sizes in the range of approximately 2–8 nm and a porosity of the protein meshwork between 30% and 70% were estimated.

Comparative studies on the distribution and uniformity of S-layers have revealed that in some species individual strains can show a remarkable diversity regarding lattice symmetry and lattice dimensions. In some organisms, two or even more superimposed S-layer lattices have been identified.

[☆]*Change History:* May 2018. Uwe B. Sleytr, A. Breitwieser and D. Pum are involved in preparing the update. The sections Abstract and Keywords, Isolation and chemical characterization, Assembly and morphogenesis, Genetics and biosynthesis, Further reading were updated. Figures 1, 3, and 4, Table 2, and relevant websites were updated. Selected milestones and historical data on S-layers research are provided in Sleytr et al. (2014) *FEMS Microbiology Reviews* 38: 823–864. This article is an update of U.B. Sleytr, P. Messner, Crystalline Cell Surface Layers (S Layers), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 89–98.

Table 1 General and specific functions of S-layers

General function	Specific function
Determination and maintenance of cell shape	Determination of cell shape and cell division in archaea that possess S-layers as exclusive wall component
Isoporous molecular sieve and antifouling coatings	Molecular sieves in the ultrafiltration range
	Delineating a compartment (periplasm) in Gram-positive bacteria
	Prevention of nonspecific adsorption of macromolecules
	Prevention of molecules reaching the cell wall proper (e.g., lytic enzymes)
Adhesion zone for exoenzymes	High-molecular-mass amylase of <i>Geobacillus stearothermophilus</i> wild-type strains
	Pullulanase and glycosyl hydrolases of <i>Thermoanaerobacter thermosulfurigenes</i>
Protective coat	Prevention of predation by <i>Bdellovibrio bacteriovorus</i> in Gram-negative bacteria
	Phage resistance by S-layer variation
	Prevention or promotion of phagocytosis
Template for fine grain mineralization	Adaptation of <i>Bacillus pseudofirmus</i> to alkaline environment
Pathogenicity and cell adhesion	Induction of precipitation of gypsum and calcite in <i>Synechococcus</i> and shedding of mineralized S-layers
	Virulence factor in pathogenic organisms
	Important role in invasion and survival within the host
	Specific binding of host molecules
	Protective coat against complement killing
	Ability to associate with macrophage and to resist the effect of proteases
	Production of immunologically non-crossreactive S-layers (S-layer variation)
Surface recognition and cell adhesion to substrates	Physicochemically and morphologically well-defined matrices
	Masking the net-negative charge of peptidoglycan-containing layer and antifouling surface in Bacillaceae

Fig. 1 Schematic illustration of the supramolecular architecture of the major classes of prokaryotic cell envelopes containing surface (S)-layers. S-layers in archaea with glycoprotein lattices as exclusive wall component are composed either of mushroom-like subunits with pillar-like, hydrophobic transmembrane domains (A), or lipid-modified glycoprotein subunits (B). Individual S-layers can be composed of glycoproteins possessing both types of membrane anchoring mechanisms. Few archaea possess a rigid wall layer (e.g., pseudomurein in methanogenic organisms) as intermediate layer between the plasma membrane and the S-layer (C). In Gram-positive bacteria, (D) the S-layer (glyco)proteins are bound to the rigid peptidoglycan-containing layer via secondary cell wall polymers. In Gram-negative bacteria, (E) the S-layer is closely associated with the lipopolysaccharide of the outer membrane. Reproduced with permission from Sleytr, U. B., Schuster, B., Egelseer, E. M. and Pum, D. (2014). S-layers: Principles and applications. *FEMS Microbiology Reviews* **38**, 823–864.

Isolation and Chemical Characterization

S-layers of different bacteria may vary considerably with respect to their resistance to disruption into their monomeric subunits, and a wide range of methods has been applied for their isolation and purification. The subunits of S-layers from the domain Bacteria interact with each other and with the supporting envelope layer through non-covalent forces.

In Gram-positive bacteria, a complete disintegration of S-layers into monomers can be obtained by treatment of intact cells or cell walls with high concentrations of hydrogen bond-breaking agents (e.g., urea or guanidine hydrochloride). Secondary cell wall

The oblique (A), square (B), and hexagonal (C) S-layer completely covers the cell surface. Bars = 100 nm.

Fig. 3 Schematic drawing of different S-layer lattice types. The regular arrays exhibit oblique (p1, p2), square (p4), or hexagonal (p3, p6) lattice symmetry. The morphological units are composed of one, two, three, four, or six identical subunits. Reproduced with permission from Sleytr, U. B., Schuster, B., Egelseer, E. M. and Pum, D. (2014). S-layers: Principles and applications. *FEMS Microbiology Reviews* **38**, 823–864.

polymers (SCWPs; sugar polymers covalently linked to the peptidoglycan of the cell wall) have been recognized as components that facilitate a specific interaction between S-layer monomers and the peptidoglycan sacculus. In bacilli, the N-terminal region was found to be responsible for anchoring the S-layer subunits to the underlying rigid cell envelope layer whereas in many lactobacilli binding occurs via the C-terminal portion in a defined orientation to the SCWP. Structurally, the SCWPs resemble to some extent teichoic acids of Gram-positive organisms but beside having the common negative charge they can also be uncharged. Therefore, at least two types of binding mechanisms between S-layer proteins and SCWPs are now considered. The first one involves so-called SLH (S-layer homology) domains and pyruvylated SCWPs. The negative charge of pyruvic acid was demonstrated to participate in binding by the construction of knockout mutants in *Bacillus anthracis* and *Thermus thermophilus*. In the case of the S-layer protein SbsB of *Geobacillus stearothermophilus* PV72/p2, the SLH domain is part of the SCWP-binding domain. The C-terminal part of SbsB turned out to be highly sensitive against deletions and even removal of <15 amino acids led to water soluble S-layer protein forms. In contrast, in SbpA, the S-layer protein of *Lysinibacillus sphaericus* CCM 2177, up to 237 amino acids from the C-terminus of that S-layer protein could be deleted without interfering with the formation of the square lattice structure. From surface plasmon resonance (SPR) measurements it is known that the binding mechanism between SLH domains and pyruvylated SCWPs is highly specific and is therefore exploited for a biomimetic approach for an oriented recrystallization of S-layer (fusion) proteins on various SCWP-coated solid supports as required for many nanobiotechnological applications.

A second type of binding mechanism between S-layer proteins and SCWPs has been described for *G. stearothermophilus* wild-type strains and involves an SCWP that contains 2,3-dideoxy-diacetamidomannuronic acid as the negatively charged component. In *Geobacillus tepidamans* an SCWP with an identical backbone structure is present but instead of a free, negatively charged carboxyl group an amide carrying different substituent is present. Therefore, this SCWP is not charged, as are the SCWPs in several *Thermoanaerobacterium thermosaccharolyticum* strains. In those S-layer (glyco)proteins that are devoid of N-terminally located SLH domains, arginine and tyrosine, which typically occur in carbohydrate binding proteins such as lectins, are accumulated in the N-terminal part.

S-layers from Gram-negative bacteria frequently disrupt upon application of metal chelating agents (e.g., ethylenediaminetetraacetic acid (EDTA) and ethylenebis(oxyethylenetriolo)tetraacetic acid (EGTA)), cation substitution (e.g., Na⁺ to replace Ca²⁺), or pH changes (e.g., pH < 4.0). From extraction and disintegration experiments it can be concluded that the bonds holding the S-layer subunits together are stronger than those binding the crystalline array to the supporting envelope layer. There are some indications that S-layers of some archaea (e.g., *Thermoproteus* species and *Methanospirillum hungatei*) are stabilized by covalent bonds between adjacent subunits.

Most S-layers are composed of a single, homogeneous protein or glycoprotein species. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) revealed apparent molecular masses for subunits in the range of approximately 40–220 kDa. In general, sequencing of the genes and mass spectrometry confirmed these results but for glycosylated S-layer proteins usually much lower molecular masses have been obtained. Amino acid analyses and genetic studies on S-layers from both archaea and bacteria have shown that the crystalline arrays are usually composed of weakly acidic proteins. Typically, they contain 40%–60% hydrophobic amino acids and possess a low portion, if any, of sulfur-containing amino acids. The isoelectric points pI are in the range of 4–6 but for *Methanothermobacter fervidus* and for lactobacilli, pI values in the range of 8–10 have been determined.

Information regarding the secondary structure of S-layer proteins is derived either from the amino acid sequence or from circular dichroism (CD) measurements, indicating that approximately 20% of the amino acids are organized as α -helices and about 40% occur as β -sheets. Aperiodic foldings and β -turn content may vary between 5% and 45%. More detailed studies have been performed with the S-layer proteins rSbsB from *G. stearothermophilus* PV72/p2 and rSbpA from *B. sphaericus* CCM 2177. Truncated forms of these S-layer proteins were constructed comprising either the N-terminal SLH domain, which is responsible for binding of the S-layer subunits to the rigid cell wall layer, or the middle and C-terminal self-assembly domain required for assembling into two-dimensional protein arrays. For both S-layer proteins, CD spectroscopy studies confirmed that most α -helical segments are arranged in the N-terminal SLH domain, whereas the middle and C-terminal parts exist as a β -sheet protein.

The fact that only a few structural models at atomic resolution of S-layer proteins are available may be explained by the molecular mass of the subunits being too large for nuclear magnetic resonance analysis, as well as by the intrinsic property of S-layer proteins to self-assemble into two-dimensional lattices, thereby hindering the formation of isotropic three-dimensional crystals, as required for X-ray crystallography. The X-ray structure of the SbsB S-layer protein of *G. stearothermophilus* PV72/p2 was determined by the use of nanobody-aided crystallization down to a resolution of 2.4 Å. The SbsB protein consists of seven domains consisting of an amino-terminal cell-wall attachment domain and six consecutive immunoglobulin-like domains which are stabilized by inter-domain Ca²⁺ ion coordination. In the case of the bacterial S-layer protein SbsC from *G. stearothermophilus* ATCC 12980, water-soluble N- and C-terminally truncated forms were used for initial crystallization experiments. Native and heavy atom-derivative data confirmed results of the secondary structure prediction, indicating that the N-terminal region comprising the first 257 amino acids of the mature S-layer protein is mainly organized as α -helices, whereas the middle and C-terminal parts of SbsC consist of loops and β -sheets. While most of the high-resolution work was done with self-assembled S-layer lattices, most recently, the structure of the hexagonal surface layer on *Caulobacter crescentus* cells was obtained in situ at a resolution of 2.7 Å.

A few post-translational modifications are known to occur in S-layer proteins, including cleavage of carboxy- or amino terminal fragments, protein phosphorylation and protein glycosylation of amino acid residues. The latter is a remarkable characteristic of many archaeal and some bacterial S-layer proteins. In fact, S-layer proteins were the first glycoproteins detected in prokaryotes and still are among the best studied examples of glycosylated prokaryotic proteins. The glycan chain and linkages of bacterial and archaeal glycoproteins are significantly different from those of eukaryotes. The *Halobacterium salinarum* S-layer glycoprotein was the

first non-eukaryotic protein shown to be *N*-glycosylated. Most archaeal S-layer glycoprotein glycans consist of only short heteropolysaccharides, usually not built of repeating units. Moreover, the predominant linkage types are *N*-glycosidic bonds where the glycan moieties are covalently linked to select asparagine residues of the target protein. Although most S-layer proteins are either *N*- or *O*-glycosylated, in few cases both modifications can be present on one protein at the same time. An example constitutes the well characterized *Halobacterium volcanii* S-layer glycoprotein contain both *N*- and *O*-linked glycans.

As mentioned before, at the same time when glycosylation on haloarchaea was reported for the first time, glycosylation of S-layer proteins from the *Bacteria* *Thermoanaerobacter thermohydrosulfuricus* and *T. thermosaccharolyticum* was discovered. Since then, S-layer glycoproteins from several other bacteria have been extensively studied, leading to the awareness of the wide distribution of S-layer glycoproteins among bacteria.

In bacteria, *N*-glycosylation is considered to be a rare event and is represented mainly in *Campylobacter* spp., *Helicobacter* spp. and *Desulphovibrio* spp. Thus, *N*-glycosylation apparently is far more common in archaea than in bacteria. The degree of glycosylation of bacterial S-layer proteins, that is, the covalent *O*-glycosidic linkage of glycan moieties to select serine, threonine, and tyrosine residues, varies generally between 2% and 10% (*w/w*) and the S-layer proteins are typically multiple glycosylated.

Moreover, the lipid carrier molecules also differ between archaea and bacteria. In archaea isoprene-based lipids like dolichol phosphate and dolichol pyrophosphate play essential roles in the *N*-glycosylation process by delivering their bound glycan cargo to selected protein targets. In bacteria, however, undecaprenol pyrophosphate is recognized to play an essential role in S-layer protein *O*-glycosylation. To sum up, S-layer glycoproteins are among the best-studied examples of glycosylated prokaryotic proteins. Hence, a more detailed and comprehensive summary cannot be given and is out of the scope of this review. Nevertheless, at this point we would like to refer to several recent reviews providing deeper information on the glycosylation process in general.

Recently, yet another post-translational modification of S-layer glycoproteins was reported. It could be demonstrated that a subset of secreted euryarchaeal proteins, including the S-layer glycoprotein, is processed and covalently linked to membrane-embedded lipids involving membrane-spanning enzymes referred to as archaeosortases.

Assembly and Morphogenesis

Isolated S-layer subunits of Gram-positive and Gram-negative bacteria have shown the ability to recrystallize on the cell envelope fragments from which they had been removed, or on those of other organisms, or on untextured charged or uncharged inanimate surfaces. To date, the most detailed self-assembly and reattachment experiments have been performed with S-layers from Bacillaceae. S-layers of these organisms reveal a high anisotropic charge distribution. The inner surface is net negatively or net positively charged, whereas the outer face is charge-neutral, approximately with pH 7. This characteristic of the S-layer subunits appears to be essential for proper orientation during local insertion in the course of lattice growth.

Detailed studies have been performed to elucidate the dynamic process of assembly of S-layers during cell growth. For maintenance of a good long-range order during cell growth, S-layer protomers must have the ability to recrystallize on the supporting envelope layer. Labeling experiments with fluorescent antibodies and colloidal gold/antibody marker methods indicated that different patterns of S-layer growth exist for Gram-positive and Gram-negative bacteria. In Gram-positives, growth of the S-layer lattice primarily occurs on the cylindrical part of the cell by insertion at multiple bands or helically arranged bands; in Gram-negatives, incorporation of new subunits occurs at random. In both types of organisms, entirely new S-layer material also appears at regions of incipient cell division and the newly formed cell poles.

Reassembly of isolated S-layer subunits at the air/water interface, on Langmuir–Blodgett (LB) films, liposomes, emulsomes, or a great variety of solid supports (e.g., polymers, silicon wafers, metals, graphene) has proven to be an easy and reproducible way for generating extended coherent S-layer lattices (Fig. 4). Moreover, S-layer proteins are ideal model system to study nonclassical nucleation and growth of protein crystals at surfaces. The self-assembly process may be divided into several stages: (i) formation of amorphous clusters that are (ii) transformed into crystalline patches. (iii) Subsequently crystal growth into extended lattices continues by the incorporation of S-layer protein subunits at the edge sites of the crystalline domains. It has to be stressed that the final conformational transformation of the monomer to the oligomeric form is an inherent part of the assembly process. In accordance with S-layer proteins recrystallized on solid surfaces, the orientation of the protein arrays at liquid interfaces was determined by the anisotropy in the physicochemical surface properties of the protein lattice. Electron microscopy and atomic force microscopy examination revealed that recrystallized S-layer proteins from Bacillaceae were oriented with their outer charge-neutral, less hydrophilic surface against the air/water interface and with their negatively charged, more hydrophilic inner surface against the positively charged or zwitterionic head groups of phospholipid or tetraether lipid films.

Genetics and Biosynthesis

The fact that S-layers fully cover the bacterial cell at all stages of growth underlines the importance of these outermost two-dimensional (2D) crystalline highly ordered arrays for the bacteria. In order to form such a closed proteinaceous layer by self-assembly on a growing cell surface, high rates of subunits must be synthesized. At a generation time of about 20 min (e.g., for bacilli), at least 500 copies of a single polypeptide species with a molecular mass of approximately 100,000 Da have to be synthesized per second.

Fig. 4 Schematic illustration of the recrystallization of isolated S-layer subunits into crystalline arrays. The self-assembly process can occur in solution, at the air–liquid interface, at the solid–liquid interface, at lipid films, on liposomes, nanocapsules, emulsomes, and on carbon nanotubes. Modified with permission (CC BY 3.0) from Pum, D., Toca-Herrera, J. L. and Sleytr, U. B. (2013). S-Layer protein self-assembly. *International Journal of Molecular Sciences* **14**, 2484–2501.

Since S-layers are ubiquitous and represent one of the most abundant cellular proteins, numerous S-layer genes from bacterial and archaeal organisms of quite different taxonomical affiliations have been sequenced and cloned in the past. The studies revealed that homologies between nonrelated organisms are low, although their amino acid compositions show no significant differences. High homology scores are usually explained by evolutionary relationships but other factors, such as growth conditions and environmental stress may also be determinative for structural homologies of S-layer genes. A homology search among the *G. stearothermophilus* S-layer protein precursors SbsA–SbsD, SgsE, and SgsF revealed that the amino acid sequences showed overall identities between 21.6% and 93.9%. Less but distinct identities were found with several S-layer proteins from related organisms, such as *Bacillus thuringiensis*, *Bacillus firmus*, *Brevibacillus brevis*, or *Clostridium thermocellum*. By comparing the amino acid sequences of the *G. stearothermophilus* S-layer proteins it became evident that they share similarities with respect to the following features: (i) they are synthesized with a typical N-terminal signal sequence consisting of 30/31 amino acids; (ii) the signal peptide cleavage site is between the Ala–Ala motif and; (iii) all S-layer proteins exhibit a weakly acidic isoelectric point.

Interestingly, within the first 270 N-terminal amino acids of these S-layer proteins, sequence identities were in the range of 82.5%–98.1%. The only exception was SbsB, which did not reveal significant sequence homology in the N-terminal region; instead, it is the only one among the compared *Geobacillus* S-layer proteins to possess SLH domains between amino acids 31 and 168.

Within the domain Archaea overall sequence comparisons have only been performed for selected organisms. Studies of methanococcal S-layers have shown that the S-layer protein of *Methanoterris igneus* shared 43% identity with *Methanothermococcus thermolithotrophicus*, 39% with *Methanocaldococcus jannaschii*, 35% with *Methanococcus vannielii*, and 34% with *Methanococcus voltae*. The S-layer protein of *Mt. igneus* possesses a 28-amino acid signal peptide with typical characteristics of signal sequences such as a positively charged N-terminal region, a hydrophobic core, a polar C-terminal region, and an alanine residue at the peptide cleavage site. Further, it is highly conserved (approximately 68%) in all S-layer proteins of *Methanococcales*.

Although the low homology for S-layer proteins on the sequence level, common structural organization principles have been identified. Two separated morphological regions could be addressed to distinct properties; one responsible for binding to the cell

wall and one required for the self-assembly. Bacillaceae possess specific binding domains on the N-terminus for SCWP. These N-terminal binding domains (SLH motifs) anchor S-layer proteins to distinct SCWPs carrying pyruvic acids.

For the S-layer of *G. stearotheophilus* PV72/p2 SbsB, recognition of SCWP by three SLH motifs could be confirmed. In *L. sphaericus* CCM2177 an additional 58-amino acid long SLH-like motif is required for attaching the S-layer to the underlying cell wall components. In contrast to the SLH motifs of most S-layer proteins, which reveal a positive net charge, those of *L. sphaericus* strains are net negatively charged, which explains the importance of bivalent cations for binding the S-layer subunits to the rigid cell envelope layer. S-layers lacking the SLH motifs are anchored to different types of SCWP via their N or C-terminal regions. Studies performed for *G. stearotheophilus* wild type strains revealed a highly conserved N-terminal region lacking a SLH domain and nonpyruvylated SCWP containing 2,3-diacetamido-2,3-dideoxymannuronic acid as the negatively charged binding site. Although no SLH motifs were found in S-layer proteins from lactobacilli, which display a variety of regions responsible for cell wall binding or self-assembly, the SCWP was found to act as counterpart anchoring the S-layers.

For understanding gene regulation of S-layer, the observation that single bacterial strains can express different genes was important. In the pathogen *Campylobacter fetus* all studies have demonstrated that only a single promoter exists and that antigenic variation is due to recombination events. This allows expression of different S-layer gene cassettes. The variation enables the organism to overcome the host's immune response.

The presence of multiple S-layer protein genes is common for lactobacilli; *Lactobacillus brevis* ATCC 14869 possess three S-layer protein genes, while for *Lactobacillus crispatus* JCM5810 and *Lactobacillus acidophilus* ATCC 4356 encoding genes for two S-layer protein genes has been described. A multiple-promoter structure has been described for several S-layer protein genes of lactobacilli. for example, two promoter regions for the S-layer protein genes of *Lactobacillus brevis* ATCC 8287 and *Lactobacillus acidophilus* ATCC 4356 are required for efficient transcription. The S-layer protein gene of *Lactobacillus brevis* ATCC 14869 was shown to be expressed differently dependent upon growth conditions. Under aerated conditions, both S-layer specific transcripts were detected, whereas under anaerobic conditions only one specific transcripts could be observed.

The genome of *B. anthracis* encompasses 24 open reading frames whose predicted translation products each contain a secretion signal and three tandem SLH domains. The *B. anthracis* gene cluster encodes the two S-layer proteins, surface array protein and extractable antigen 1, as well as a pyruvyl transferase responsible for decorating SCWP with ketal-pyruvate.

An intact, "closed" S-layer on an average-sized, rod-shaped cell consists of approximately 5×10^5 monomers, the biogenesis of which requires high amounts of metabolic resources. S-layer monomeric proteins must be generated, hindered to self assemble within the cells during translocation to the cell surface and there rapidly incorporated into the existing S-layer lattice. Bacteria exhibit distinct secretory pathways for the secretion and anchoring of the S-layer to the cell wall. In many Gram-positive bacteria (described in detail for *Clostridium difficile* and *B. anthracis*) secretion of the S-layer precursors is dependent on the accessory Sec secretion system, which appears to involve one or two major S-layer proteins as well as S-layer-associated proteins. Precursors can travel via the canonical secretory pathway involving SecA or a SecA2 pathway responsible for the secretion of S-layer proteins.

Here the amino terminal signal peptide of the S-layer protein directs the polypeptide to the secretion apparatus and is cleaved upon membrane translocation. The accessory ATPase SecA2 is required to guide the S-layer proteins across the cytoplasmic membrane through distinct pores. The *C. difficile* S-layer is composed of two proteins, which are produced by proteolytic cleavage of the precursor S-layer protein SlpA. The low molecular weight S-layer protein, which probably faces the environment, shows considerable sequence variability among strains generating antigenic diversity. Another *C. difficile* S-layer protein, cell wall protein V, undergoes phase-variable expression, leading to phenotypic heterogeneity in the population.

In several Gram-negative bacteria S-layer secretion is based upon a type I secretion system. for example, in *C. fetus* and *C. crescentus* secretion is performed with an inner membrane ATP-binding cassette (ABC transporter) in combination with an outer membrane pore. Secretion of the S-layer proteins in the fish pathogens *Aeromonas salmonicida* and *Aeromonas hydrophila* relies on a specific two-step type II secretion system. Here, the unfolded precursor is translocated across the cytoplasmic membrane by the canonical Sec secretion system followed by folding of the protein and transportation across the outer membrane under the support of a multi-protein secretion apparatus.

An interesting feature is that many bacterial and most archaeal S-layer proteins are glycosylated. Although the function of bacterial S-layer glycoprotein glycans is still unclear so far, the enormous biosynthesis effort by various bacteria from different phylogenetic branches to glycosylate their S-layer proteins can lead to the assumption that glycosylation adds significantly to the potential functional spectrum of S-layer proteins.

The remarkable diversity in glycan structures of S-layer glycoproteins raised interesting questions about the biosynthesis of prokaryotic glycoproteins. In the domain Bacteria, four complete and one incomplete *slg* (surface-layer glycosylation) gene clusters have been identified. Slg gene clusters have been originally found based on the presence of L-rhamnose in the respective S-layer glycans and the knowledge that the *rmlABCD* genes involved in biosynthesis of L-rhamnose are highly conserved among Gram-positive and Gram-negative bacteria.

A polycistronic *slg* gene cluster encodes the S-layer glycan biosynthesis in *G. stearotheophilus* NRS 2004/3a. Three rhamnosyl-transferases are responsible for the transfer of L-rhamnose from a nucleotide diphosphate-activated precursor across the membrane by a process involving an ABC transporter to the growing S-layer glycan chain. It seems that the variable part in the center of the *slg* gene clusters is responsible for the biosynthesis of the individual repeating units and terminating elements, whereas the region with higher homology codes for proteins involved in assembling the core region, transport of the glycan to the cell surface, and its ligation to the S-layer protein.

A bacterial protein tyrosine O-glycosylation system was described for the S-layer glycoproteins of *T. thermohydrosulfuricus* strains S102-70 and L111-69, *Th. thermosaccharolyticum* strains D120-70 and E207-71, and *Pa. alvei* CCM 2051^T in which glycan chain might be synthesized in a process similar to the ABC transporter-dependent pathway of the LPS O-PS biosynthesis.

In contrast to the previously described long-glycan chain S-layer glycoproteins of thermophilic and mesophilic bacilli, short-glycan chain S-layer glycoproteins have also been described for the Gram-positive organism *La. buchneri* CD034 or the Gram-negative periodontal pathogen *Tannerella forsythia* ATCC 43037.

In the following study, for the first time a glycosylated S-layer protein has been described for a Gram-negative organism. The newly emerged periodontopathogenic pathogen *T. forsythia* possesses an S-layer protein that is involved in hemagglutination, adhesion/invasion of epithelial cell, and murine subcutaneous abscess formation. The structure of the glycan partially imitates that of host glycoproteins and the glycobiology of this pathogen, including its repertoire of glycosidases, seems to be key to its physiology and, potentially, pathogenicity. Biochemical and molecular genetic characterization revealed that the S-layer is composed of two different glycosylated proteins *TfsA* and *TfsB*. Amino acid sequence comparison exhibited a 24% similarity between the two, 200 and 210 kDa proteins. Further sequence analyses showed that both possess putative signal peptide sequences with cleavage sites at alanine residues, and transmembrane domains on the C-terminal region. Comparison with other known S-layer proteins of prokaryotic organisms shows that the *T. forsythia* S-layer is very unique, since it appears to be composed of two large glycoproteins, and it does not reveal any homology to other known S-layer proteins or glycoproteins of prokaryotic organisms.

Very recently, a glycosylated S-layer was shown to be present also on the anamox bacterium candidate *Kuenenia stuttgartiensis*. This S-layer showed hexagonal symmetry, which has no homology to any known protein and is present in glycosylated form.

Work on the identification of genes involved in the biosynthesis and attachment of *Methanococcus voltae* glycans provided the first detailed insights into N-linked glycosylation pathways in archaea at the genetic level. In addition to the previous work on halophilic archaea, a novel trisaccharide N-linked to asparagine residues in *Methanococcus voltae* flagellin and S-layer proteins could be characterized. Several candidate genes within the *Methanococcus voltae* genome were inactivated by insertional mutagenesis and have effects on flagellin and S-layer protein molecular mass, the N-linked glycan structure and are further involved in the transfer of the complete glycan to the flagellin and S-layer proteins.

Functional Aspects and Application Potential

Since S-layers represent one of the few examples in nature where proteins reveal the intrinsic capability to self-assemble into closed monomolecular lattices, a considerable potential in biological and nonbiological applications is evident. Data obtained in fundamental studies demonstrated that S-layers represent an ideal patterning element for nanobiotechnological, biomimetic, and nanotechnological applications. Particularly, the repetitive physicochemical properties and isoporosity of S-layer protein lattices down to the subnanometer scale make them unique matrices and building blocks for generating complex and supramolecular assemblies. The prime attractiveness of such “bottom-up” strategies lies in their capability to generate uniform nanostructures, and the possibility to exploit such structures at the meso- and macroscopic scale. Most importantly, it has been shown that S-layers can be combined with all major species of biological or synthesized (macro)molecules. Particularly, cloning and characterization of genes encoding S-layer proteins opened new areas of applied S-layer research as the incorporation of single or multifunctional domains has been possible without loss of their self-assembly capabilities (Table 2). As S-layers are highly anisotropic structures with regard to their topography and the physicochemical properties of their inner and outer surface, it was essential to ensure the recrystallization of S-layer fusion proteins in defined orientation on solid supports (e.g., polymers, metals, semiconductors), lipid membranes, and liposomes. Biomimetic approaches copying the physicochemical properties of the cell envelope structures supporting native S-layer proteins (e.g., SCWP, peptidoglycan) provided a remarkably easy solution for this problem. S-layer lattices are also used as support and stabilizing structures for lipid membranes and liposomes, mimicking the supramolecular construction principle of archaea dwelling under extreme environmental conditions (Fig. 1A and B) or virus envelopes. This technology allows exploitation of specific membrane functions with different formats while considerably increasing the life-time of the membranes as required for biosensors, lipid chips, drug screening, diagnostics, targeting, and drug delivery systems. S-layer self-assembly products have also been demonstrated to be well suited for a geometrically defined attachment of haptens and immunogens or immunostimulating and immunomodulating substances. Moreover, it is expected that highly specific immunogenic components with intrinsic targeting and delivery functionalities can be developed by combining recombinant S-layer proteins with the supramolecular construction principle of virus envelopes.

Chemical analyses of different S-layer proteins have demonstrated the presence of covalently linked carbohydrate residues. Since cell surface glycoconjugates play critical roles in many biological processes, in organisms from bacteria to man, glycosylated S-layers are a promising means for the development of functionalized nanoscaled materials. The detailed knowledge of glycoprotein biosynthetic pathways and cloning of the involved key enzymes are a prerequisite for the exploitation of glycobiology within the fields of nanobiotechnology (e.g., glycotherapeutics with controllable, nanometer-scaled display of epitopes). Engineering of tailor-made bacterial glycoproteins will decisively change our capabilities in influencing and controlling complex biological systems (e.g., control of serum half-life of glycosylated metabolites and interference with glycosylated receptors).

Table 2 Functional recombinant S-layer fusion proteins and their applications

Recombinant S-layer protein	Functionality	Length of function	Application
SbpA SbsB	Core streptavidin	118 aa	Binding of biotinylated ligands (DNA, protein), Biochip development
SbpA, SbsC	Major birch pollen allergen (Bet v1)	116 aa	Vaccine development, treatment of type 1 allergy
SbpA	Strep-tag II, Affinity tag for streptavidin	9 aa	Biochip development
SbpA	ZZ, IgG-binding domain of Protein A	116 aa	Extracorporeal blood purification
SbpA	Enhanced green fluorescent protein (EGFP)	238 aa	Coating of liposomes, development of drug and delivery systems
SbpA	cAb, heavy chain camel antibody	117 aa	Diagnostic systems and sensing layer for label-free detection systems
SbpA	Hyperthermophilic enzyme laminarinase (LamA)	263 aa	Immobilized biocatalysts
SbpA	Cysteine mutants	3 aa	Building of nanoparticle arrays
SbpA, SbsB	Mimotope of an Epstein-Barr virus (EBV) epitope (F1)	20 aa	Vaccine development
SbpA, SbsB	<i>Mycobacterium tuberculosis</i> antigen (mpt64)	204 aa	Vaccine development
SbpA	IgG-binding domain of Protein G	110 aa	Downstream processing
SgsE	Glucose-1-phosphate thymidyltransferase (RmlA)	299 aa	Immobilized biocatalysts
SgsE	Enhanced cyan fluorescent protein (ECFP)	240 aa	pH biosensors in vivo or in vitro, fluorescent markers for drug delivery systems
	Enhanced green fluorescent protein (EGFP)	240 aa	
	Yellow fluorescent protein (YFP)	240 aa	
	Monomeric red fluorescent protein (RFP1)	225 aa	
SbsA	<i>Haemophilus influenzae</i> antigen, (Omp26)	200 aa	Vaccine development
SlpA	Antigenic poliovirus epitope (VP1)	11 aa	Development of mucosal vaccines
	Human c-myc proto-oncogene	10 aa	
	Levansucrase of <i>B. subtilis</i>	473 aa	
SLH-EA1, SLH-Sap	Tetanus toxin fragment C of <i>Clostridium tetani</i> (ToxC)	451 aa	Vaccine development
SLH-EA1			Development of live veterinary vaccines
RsaA	<i>Pseudomonas aeruginosa</i> strain K pilin	12 aa	Vaccine development
RsaA	IHNV glycoprotein	184 aa	Development of vaccines against hematopoietic virus infection
RsaA	Beta-1,4-glycanase (Cex)	485 aa	Immobilized biocatalysts
RsaA	IgG-binding domain of Protein G	GB1 _{xs}	Development of immunoactive reagent
RsaA	Domain 1 of HIV receptor CD4	81 aa	Anti-HIV microbicide development
	MIP1 α ligand for HIV coreceptor CCR5	70 aa	
RsaA	His-tag, Affinity tag	6 aa	
RsaA	Protective coat	6 aa	Bioremediation of heavy metals (Cd) from aqueous systems, bioreactor
			Protection against antimicrobial peptide in <i>Caulobacter crescentus</i>

S-layer proteins: SbsB of *Geobacillus stearothermophilus* PV72/p2, SbpA of *Lysinibacillus sphaericus* CCM 2177, SbsC of *Geobacillus stearothermophilus* ATCC 12980, SgsE of *Geobacillus stearothermophilus* NRS 2004/3a, SbsA of *Bacillus stearothermophilus* PV72/p6, SlpA of *Lactobacillus brevis* ATCC 8287, SLH (S-layer homology domain of EA1 or Sap) of *Bacillus anthracis*, RsaA of *Caulobacter crescentus* CB15A, * personal communication.

Another line of development is directed to the use of S-layer lattices for non-life science applications. It has already been shown that S-layer protein meshworks can be exploited for biological templating, biomineralization, and the formation of arrays of metal clusters and nanoparticles as required in molecular electronics, biocatalysis, and nonlinear optics. Recently, it was demonstrated that fabrication of spatially well-defined ordered S-layer arrays on silicon support can be achieved by applying micromolding in capillaries (a soft lithography technique).

Finally, S-layers as isoporous structures can be used for the production of ultrafiltration membranes with very sharp molecular exclusion limits. These membranes are manufactured by depositing and cross-linking S-layer fragments on microfiltration membranes.

Although a remarkably broad spectrum of nanobiotechnological applications for S-layers has already been developed, many other areas will eventually emerge. Particularly, data on specific biological functions and biophysical properties of S-layers of organisms growing and surviving under extreme environmental conditions will stimulate applied S-layer research and broaden the application potential.

Cutaneous Host Defenses

Structure of the Skin

The physical and chemical structure of the skin represents a form of defense against fungal pathogens. The skin surface is relatively inhospitable to fungal growth because of exposure to ultraviolet light, low moisture conditions, and competition from the normal bacterial flora of this site. Therefore, this surface acts as a barrier to the entry of fungi. The stratum corneum is made up of keratin, which most microorganisms cannot use for nutrition. However, *Candida albicans* and the dermatophytic fungi produce keratinases, which hydrolyze this substance and facilitate the growth of these organisms in the stratum corneum itself. This very superficial site of infection may protect the infecting organisms from direct contact with at least some of the effector cells of the immune system. Although neutrophils and small numbers of lymphocytes may enter the epidermis, the major infiltrates of cell-mediated immune responses are generally confined to the dermis.

Keratinization and Epidermal Proliferation

The process by which the stratum corneum is continually renewed through keratinization of the epidermal cells may also present a form of defense against organisms infecting the skin. The basal epidermal cells cause continued growth of the epidermis as they undergo repeated cell divisions that move the resulting daughter cells (keratinocytes) outward, toward the surface. As they mature and differentiate, these cells lose their nuclei and become flattened to form the keratinized cells. This process results in continuous shedding of the stratum corneum, which may remove infecting fungal microorganisms residing there. Inflammation, including that produced by cell-mediated immune reactions, appears to enhance epidermal proliferation so that rates of transit of epidermal cells toward the stratum corneum are increased. A number of studies have demonstrated that epidermal proliferation is important in the defense against superficial mycosis.

Antifungal Substances

Sebaceous gland secretions and other epidermal lipids, including the sphingosines, fatty acids, polar lipids, and glycosphingolipids, have been shown to be fungistatic against both dermatophytes and *C. albicans*. Unsaturated transferrin is another well-known antimicrobial substance that appears to be active in inflamed skin and inhibits microbial growth by competing for iron. Keratinocytes of the epidermis produce several other antimicrobial proteins, including cathelicidins, human β -defensin 2, and calprotectin. These proteins appear to be generated in greater quantities when the keratinocytes are stimulated by contact with microorganisms or cytokines. A variety of other antimicrobial proteins are also found in the skin, including granzyme B, adrenomedullin, antileukoprotease, and melanins. Others are undoubtedly present also, and the presence of all these antimicrobial compounds adds to the difficulty that potential pathogens face when trying to invade into the skin.

The Innate Immune System

The innate immune system is composed of cells and mechanisms that defend an organism against nonself entities in a nonspecific manner; it represents a first line of defense against invading pathogens and does not require a preliminary exposure to microbial antigens to generate an effective response. Unlike adaptive immunity, the innate immune system does not confer long-lasting memory or protective immunity against the foreign entity. Rather, innate immunity provides immediate defense against pathogens. This system is especially prominent in those body surfaces that contact the external environment and are colonized by potential pathogens; these areas include the skin, digestive and urinary tracts, and airways. Therefore, cutaneous fungal pathogens must somehow evade these processes when they first try to invade the skin.

All known plants and animals have innate immunity, suggesting that this system appeared early during evolution. The major function of this system seems to be the initial recruitment of leucocytes, such as macrophage and neutrophils, to areas of infection. These cells then phagocytose and kill pathogens while also eliciting continued inflammatory responses. After microbial killing occurs in the phagosomes of macrophage, the organism's components may also be presented to T lymphocytes to activate the adaptive immune system. Thus, there is interplay between these two arms of the immune system.

A critical part of this process is the ability of the host cells to discriminate between themselves and a large number of potential pathogens using a restricted number of germ-line-encoded pattern recognition receptors. The latter recognize particular chemical

[☆]Change History: August 2014. E Khan and PG Sohnle have updated the abstract, the sections on innate immunity, cutaneous candidiasis, pityriasis versicolor, Table 2, and the Reference section.

This article is an update of C.J. Watts, D.K. Wagner, P.G. Sohnle, Fungal Infections, Cutaneous, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 382–388.

characteristics of microorganisms, referred to as pathogen-associated molecular patterns (PAMPs). The best-described host receptors involved in this process are the toll-like receptors (TLRs), whose genes are present in all eukaryotes. At present there are ten known TLRs in humans, with different PAMPs being recognized by different ones. Other similar receptors include Nod-like receptors (NLRs), RIG-I-like receptors (RLRs), and C-type lectin receptors (CLRs). Once the pattern recognition receptor identifies a PAMP, it begins a cell-signaling cascade that initiates a defensive response directed at eliminating the pathogen. This cascade involves multiple cytokines that promote inflammation, stimulate adaptive immunity, and cause an acute phase response. Factors such as age, nutritional status, and hormone levels may alter innate responses.

The Inflammatory Response

With various kinds of superficial fungal infections, there appears to be an inverse relationship between the degree of inflammation produced by a particular fungal pathogen and the chronicity of that infection. *Malassezia sp.* and the anthropophilic dermatophytes, *Trichophyton rubrum* and *Epidermophyton floccosum*, generally produce little inflammation in their cutaneous lesions and frequently cause infections that persist for long periods. On the other hand, many of the geophilic or zoophilic dermatophytes, for example, *Trichophyton verrucosum*, produce highly inflammatory infections that are usually self-limited. Thus, the local inflammatory process may indeed be involved in the defense against this group of pathogens.

Several mechanisms have been described by which inflammatory cells are attracted into sites of cutaneous fungal infections, in addition to the innate immunity processes described above. Fungal organisms are generally capable of activating complement by the alternative pathway to produce chemotactic activity for neutrophils and can also produce low molecular weight chemotactic factors analogous to the ones made by growing bacteria. Keratinocytes themselves can generate chemotactic cytokines that could also be responsible for some of the inflammation in the lesions of cutaneous fungal infections.

Neutrophils and monocytes/macrophage appear to be important in the defense against fungi, including those involved in the cutaneous mycoses. Neutrophils can directly attack pathogens using a variety of microbicidal processes. These processes depend upon either microbicidal oxidants or nonoxidative granule antimicrobial peptides. The latter include defensins, bactericidal/permeability-increasing protein, lactoferrin, lysozyme, and cathelicidin. Most of these compounds have been studied primarily for their ability to kill organisms, although lactoferrin may have both microbistatic and microbicidal effects. Macrophages have an additional antimicrobial mechanism whereby they can produce nitric oxide to inhibit growth of ingested fungal pathogens. Neutrophils also appear to have significant growth inhibitory activity in their cytoplasm. These cells, as do the keratinocytes themselves, produce large amounts of calprotectin, a calcium- and zinc- binding protein that has potent microbistatic activity against *C. albicans*, the dermatophytes, and other fungi.

The Cutaneous Immune System

Since cutaneous fungal infections are more frequent and more severe in patients with immunologic defects, immune responses to fungal antigens would seem to play an important role in the host defense against these infections. Immunologic host defense mechanisms in normal hosts seem to be effective even when the infections are limited to superficial locations, such as the stratum corneum. A number of studies suggest that the epidermis not only represents a passive barrier against the entry of infecting organisms, but also acts as an immunologic organ with some unique elements. The skin-associated lymphoid tissue (SALT) appears to act as immune surveillance unit. A variety of cell types are believed to be involved in this cutaneous immune system, including Langerhans cells, dermal dendritic cells, epidermal T lymphocytes, keratinocytes, and microvascular endothelial cells. The mechanisms employed are complex, involving a network of fixed or mobile cells interacting either by the trafficking of the cells themselves from one site to another or by the production of cytokines that influence the function of other cells. Such skin-initiated immune responses act against a broad spectrum of foreign antigens including contact allergens, tumors, and transplants, and it is likely that they are also active against the fungal pathogens of interest here. Therefore, this system is probably responsible for initiating immune responses that work to eliminate the infecting organisms in the immune host. In addition, such responses may also produce some of the inflammation that results in much of the symptomatology of these infections.

Description of the Diseases

Superficial Fungal Infections

These infections are limited to the most superficial layers of the epidermis and/or its keratinized appendages, such as the hair and nails. The most common pathogens causing superficial mycoses are listed [Table 1](#).

Cutaneous candidiasis

Cutaneous candidiasis is an infection of the skin that is generally caused by the yeast-like fungus *C. albicans* and that can be either acute or chronic in nature. *C. albicans* is part of the normal flora of the gastrointestinal tract, rather than that of the skin, although it can be found on the skin on occasion. This organism can grow as either yeast cells or filamentous forms, with mixtures of the two phases generally seen in tissue infections. Cutaneous candidiasis on occasion may be caused by other species of this genus, including *Candida parapsilosis*, *Candida tropicalis*, or *Candida glabrata*, but these are unusual.

Table 1 Superficial cutaneous mycoses and the most common responsible pathogens

Type of infection	Pathogens
A. Cutaneous candidiasis	<i>Candida albicans</i>
Dermatophytosis	Trichophyton, Microsporum, Epidermophyton
1. Tinea pedis	<i>T. rubrum</i> , <i>T. mentagrophytes</i> , <i>E. floccosum</i>
2. Tinea cruris	<i>E. floccosum</i> , <i>T. rubrum</i>
3. Tinea barbae	<i>T. rubrum</i> , <i>T. verrucosum</i> , <i>T. mentagrophytes</i>
4. Tinea unguium (onychomycosis)	<i>T. rubrum</i> , <i>T. mentagrophytes</i>
5. Tinea capitis	<i>T. tonsurans</i> , <i>T. schoenleinii</i> , <i>T. rubrum</i> , <i>M. canis</i> , <i>M. audouinii</i>
6. Tinea corporis	<i>T. rubrum</i> , <i>T. mentagrophytes</i> , <i>M. canis</i> , <i>T. verrucosum</i> , <i>M. gypseum</i>
Skin and nail infections by nondermatophytes	<i>Scytalidium dimidiatum</i> , <i>Scopularia brevicaulis</i> , <i>Fusarium oxysporum</i>
Tinea versicolor	<i>Malassezia globosa</i> , <i>M. furfur</i> , <i>M. sympodialis</i>
Malassezia folliculitis	<i>Malassezia</i> sp.
Tinea nigra	<i>Hortaea werneckii</i>
White piedra	<i>Trichosporon ovoides</i> , <i>T. inkin</i> , <i>T. asahii</i>
Black piedra	<i>Piedraia hortae</i>

Acute cutaneous candidiasis may present as intertrigo, producing intense erythema, edema, creamy exudates, and satellite pustules within folds of the skin. Other infections may be more chronic, as in the feet where there can be a thick white layer of infected stratum corneum overlaying the epidermis of the interdigital spaces. Candida paronychia is marked by infection of the periungual skin and the nail itself, resulting in the typical swelling and redness of this type of candidal infection.

Superficial candidiasis is common in otherwise healthy neonates and young infants, and mainly manifests as either oropharyngeal candidiasis (oral thrush) or candidal diaper dermatitis. In the latter case, moist macerated skin in the diaper area appears to be particularly susceptible to candida invasion. The infection usually starts in the perianal region and may spread to involve the perineum and perhaps the lower abdomen and upper thighs. The lesions are typically scaly papules that progress to weeping eroded lesions that often have satellite pustules. Congenital cutaneous candidiasis is a more severe infection of neonates wherein the disease presents within 6 days of birth; there is generally widespread desquamation and/or erosive dermatitis and a significant risk of systemic and sometimes fatal candida infection. The affected neonates require systemic antifungal therapy.

In some cases, superficial *C. albicans* infections may be particularly severe, persistent, and recalcitrant to treatment, producing the uncommon disorder known as chronic mucocutaneous candidiasis. This condition consists of persistent and recurrent infections of the mucous membranes, skin, and nails, along with a variety of other manifestations. The superficial infections last for years in affected patients unless they are properly treated, although deep candida infections are very rare in this situation. Oral thrush and candida vaginitis are fairly common in patients with chronic mucocutaneous candidiasis. There is often infection of the esophagus, although further extension into the viscera is unusual. Epidermal neutrophilic microabscesses, which are common in acute cutaneous candidiasis, are rare in the lesions of chronic mucocutaneous candidiasis. The oral lesions are generally tender and painful.

A number of other disorders are associated with the syndrome of chronic mucocutaneous candidiasis, including endocrine dysfunction, vitiligo, dysplasia of the dental enamel, congenital thymic dysplasia, thymomas, and certain other infections. The term autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) has been used to describe some of these patients, and mutations in a particular gene, called the autoimmune regulator (AIRE), appear to be responsible. More recently, some patients with chronic mucocutaneous candidiasis have been demonstrated to have a deficiency in IL17 cytokine production, which is the function of a recently described subdivision of T cells (Th17 cells) with important proinflammatory and host defense functions. In addition, a family with mucocutaneous candidiasis was found to have a mutation in the CARD9 (caspase recruitment domain-containing protein 9) gene that was associated with low numbers of Th17 cells in the affected family members. The Th17 pathway appears to be important in protecting against chronic superficial candida infections. Otherwise, chronic mucocutaneous candidiasis no doubt represents a group of related syndromes with a variety of predisposing or secondary abnormalities in host defense function, most commonly deficient cell-mediated immune responses against candida antigens.

The diagnosis of superficial candidiasis is usually suspected on clinical grounds and can be confirmed in skin scrapings by demonstrating the organisms using potassium hydroxide preparations and/or culture on appropriate antifungal media. Long-term (3–9 months) treatment with azole antifungal drugs can produce good results in chronic mucocutaneous candidiasis, although occasional failures have occurred due to the development of resistant strains of *C. albicans*. Patients who present with chronic mucocutaneous candidiasis should be evaluated for the presence of infection with the human immunodeficiency virus and, if presenting as adults, for the possibility of thymoma.

Dermatophytosis

Dermatophytosis is the infection of keratinized structures, such as the nails, hair shafts, and stratum corneum of the skin, by organisms of three genera of fungi termed dermatophytes. Although they are not part of the normal human skin flora, these organisms are particularly well adapted to infecting this location because they can use keratin as a source of nutrients – unlike most

other fungal pathogens. The different types of dermatophytes are often classified according to body site, using the word 'tinea', followed by a term for the particular body site. The major types of dermatophytosis and the most frequent organisms associated with them are listed in Table 1. The degree of inflammation produced in the lesions appears to depend primarily on the particular organism and perhaps also to some extent on the immunological competence of the patient.

Tinea pedis (athlete's foot) is probably the most common form of dermatophytosis. This condition is a chronic toe web infection that can be scaly, vesicular, or ulcerative in form and can sometimes produce hyperkeratosis of the sole of the foot. Tinea cruris is an expanding dermatophyte infection in the flexural areas of the groin and occurs much more frequently in males than in females. Dermatophyte infection of the major surface areas of the body is termed tinea corporis. These infections frequently take the classical annular, or 'ringworm', shape. Involvement of the beard area in men, a condition known as tinea barbae, is often caused by zoophilic organisms such as *T. verrucosum*. Infection of the hair and skin on the scalp is called tinea capitis and is more common in children than adults. Hair infection by dermatophytic fungi can be classified as either endothrix (with organisms present within the hair shaft) or ectothrix (with most of the organisms outside the hair shaft, forming a sheath of spores around it).

Tinea unguium is a form of onychomycosis, or fungal infection of the nails, that is caused by dermatophytes such as *T. rubrum*. This type of infection may be classified into three types by the way the organisms enter the nails: (1) distal subungual onychomycosis, in which the organisms initially enter the distal nail plate and nail bed; (2) proximal subungual onychomycosis, in which the organisms invade proximally in the cuticle area and then migrate distally; and (3) white superficial onychomycosis, in which the fungi invade the superficial layers of the nail plate directly. Nail infections, particularly of the toenails, are among the most difficult types of dermatophytosis to treat.

Diagnosis of dermatophytosis is made in a similar manner to that of cutaneous candidiasis, with examination of skin scrapings by potassium hydroxide preparations and culture on appropriate fungal media. The treatment of this condition has improved markedly in recent years with the development of new antifungal agents for topical application or oral administration. However, certain kinds of dermatophytosis, including widespread infections and those of hair and nails, will often respond poorly to topical therapy and will require prolonged courses of an oral antifungal agent, such as griseofulvin, ketoconazole, itraconazole, fluconazole, and terbinafine.

There is an opportunistic fungal organism, *Scytalidium dimidiatum* (formerly known as *Hendersonula toruloidea*), that can produce conditions clinically mimicking those caused by the usual dermatophyte species, but which does not respond well to conventional antifungal therapy. In addition, some nondermatophytic fungi such as *Scopulariopsis brevicaulis* and *Fusarium oxysporum* can invade the nails to produce the white superficial onychomycosis pattern of infection. Whereas dermatophytes rarely invade the deep tissues or produce systemic infections, even in severely immunocompromised patients, *Fusarium* spp. can disseminate to produce severe and often fatal infections in patients with inadequate host defenses. On the other hand, deep and severe dermatophytosis caused by the usual dermatophytes has been found in some families with inherited CARD9 deficiency.

Tinea (pityriasis) versicolor and malassezia folliculitis

Tinea versicolor is a chronic superficial fungal infection of the skin generally affecting the trunk or the proximal parts of the extremities and caused by various species of *Malassezia*, primarily *M. globosa*, *M. furfur*, and *M. sympodialis*. The organism is lipid requiring and will not grow on most laboratory media. The lesions resulting from infection with *Malassezia* sp. are macules that may coalesce into large, irregular patches characterized by fine scaling, along with hypopigmentation or hyperpigmentation. These infections can persist for years unless treated appropriately. *Malassezia* sp. have also been postulated to play a role in certain other diseases, including atopic dermatitis, seborrheic dermatitis, psoriasis, and reticulate papillomatosis. *Malassezia* folliculitis is a condition that resembles several other cutaneous infections, including acne vulgaris, the macronodular lesions of disseminated candidiasis in immunosuppressed patients, the candidal papular folliculitis of heroin addicts, and graft-versus-host disease in bone marrow transplant patients. The papules of this condition begin as inflammation of the hair follicles, instead of macules typical of tinea versicolor, and may progress to frank pustules.

In tinea versicolor, potassium hydroxide preparations of skin scrapings reveal the typical grape-like clusters of yeast and tangled hyphae of the causative fungus, confirming the diagnosis of this condition. The organism is not usually cultured because of the requirement for specialized media. Tinea versicolor can be treated topically with lotions or creams containing selenium or sodium thiosulfate, specific antifungal agents, or sulfur-salicylic acid shampoo. Oral azole antifungal drugs can also be used for more difficult cases. *Malassezia* folliculitis can be treated using topical antifungal agents or an oral azole antifungal agent.

Miscellaneous superficial fungal infections

Tinea nigra is a superficial mycosis of the palms that is most often caused by *Hortaea werneckii* (formerly called *Phaeoannellomyces werneckii* or *Exophiala werneckii*). The lesions are generally dark-colored, nonscaling macules that are asymptomatic, but can be confused with melanomas and can perhaps result in unnecessary surgery. Tinea nigra is most often seen in tropical or semitropical areas of Central and South America, Africa, and Asia, although some cases do occur in North America. This condition can be treated effectively with either keratinolytic agents or topical azoles. White piedra is an asymptomatic fungal infection of the hair shafts that is caused by *Trichosporon beigelii* (also known as *Trichosporon cutaneum*). This infection produces light-colored, soft nodules on the hair shafts and may cause the involved hairs to break. Otherwise, this condition appears to be asymptomatic, although the causative fungus can produce serious infections in immunocompromised patients. Black piedra is similar to white piedra in that it is a nodular, generally asymptomatic, fungal infection of the hair shafts. It is caused by *Piedraia hortae* and most commonly affects the scalp hair. Black and white piedra are generally treated by clipping off the affected hairs.

Cutaneous and Subcutaneous Mycoses

The dermis and subcutaneous tissues can be infected by a variety of fungal agents that are directly implanted into the skin by punctures with sharp objects contaminated by the organisms. Organisms causing the deep cutaneous and subcutaneous mycoses are listed in Table 2.

Sporotrichosis

This condition is generally caused by accidental implantation of the causative fungus *Sporothrix schenckii* into the skin. The lesions most often consist of cutaneous and subcutaneous nodules extending up the limb from the site of inoculation. However, spread may occur through the lymphatics or blood vessels, causing infections of the bones, joints, or other organs. It is also possible to develop lesions in the lungs by inhalation of the fungal elements. The causative organism is a dimorphic fungus that exists as either hyphae or elongated yeast cells.

The most common reservoir of the fungus in nature is on vegetation, although it may also be found in the soil. Rose bushes often have the organism, and inoculation by rose thorn punctures is common. The site of implantation may develop into a papule or pustule and cutaneous nodules may then develop proximally in a linear fashion. If the fungus is inhaled, it may cause a granulomatous pneumonitis that can cavitate and produce a clinical picture similar to tuberculosis. Immunosuppressed patients are more likely to develop disseminated disease.

Demonstration of the characteristic small, cigar-shaped yeast cells is diagnostic but often difficult. Multiple sections may have to be examined. Asteroid bodies are stellate, periodic acid–Schiff (PAS)-positive eosinophilic material that surround the organisms. The diagnosis of sporotrichosis is best made by culture of material from the lesions on appropriate fungal media. Isolation of this organism is usually indicative of sporotrichosis in that the fungus is not part of the normal flora of humans. Iodides may be given for cutaneous sporotrichosis, with oral itraconazole or fluconazole being used if these measures fail. For disseminated disease, either amphotericin B or itraconazole is generally effective, although relapse is common.

Chromoblastomycosis

Certain species of the dematiaceous (darkly pigmented) fungi can cause chronic cutaneous and subcutaneous infections. A number of genera can be involved, but *Fonsecaea*, *Phialophora*, and *Cladophialophora* are most common. The dark pigment of these organisms is dihydroxyphenylalanine melanin also associated with *Cryptococcus neoformans*. Dematiaceous fungi can also cause mycetoma and phaeohyphomycosis (see below). Chromoblastomycosis is characterized by the presence of sclerotic (muriform) bodies in the tissues. Chromoblastomycosis usually results from implantation of the organisms during local trauma, generally to the feet or legs. Usually, the first lesion is an erythematous papule, followed by scaling and crusting, with eventual development into a warty structure. The pathology is characteristic of a suppurative granuloma, often with overlying pseudoepitheliomatous hyperplasia. The distribution of cases is worldwide, although most come from Central and South America.

The finding of the characteristic cross-walled, pigmented sclerotic bodies is pathognomonic of chromoblastomycosis. However, since those formed by all the relevant dematiaceous fungal species are similar, culture of the infecting organism on fungal media containing cycloheximide and antibiotics is necessary to identify it. Treatment may be difficult in that the organisms may not be sensitive to antifungal agents. Surgery or local heat may be other options in the early stages of the disease.

Phaeohyphomycosis

Dematiaceous fungi can also cause this closely related condition, with *Exophiala jeanselmei*, *Wangiella dermatitidis*, and *Bipolaris* sp. being most common. These infections usually begin as papules with indolent and painless spread into the subcutaneous tissue, sometimes with cyst formation. However, especially in immunosuppressed patients, the organisms can spread to sinuses, lungs, and brain; it should be noted that brain abscesses have occurred in immunocompetent patients. Surgical debridement may be necessary for cure of these infections. In deep infections such as brain abscess, amphotericin B has been used with some success. Otherwise, the newer azoles such as voriconazole or posaconazole may have a role also.

Table 2 Deep cutaneous and subcutaneous mycoses and the most common responsible pathogens

Type of infection	Pathogens
A. Sporotrichosis	<i>Sporothrix schenckii</i>
B. Chromoblastomycosis	<i>Fonsecaea pedrosoi</i> , <i>F. compacta</i> , <i>Cladophialophora carrionii</i> , <i>Phialophora verrucosa</i>
C. Phaeohyphomycosis	<i>Exophiala jeanselmei</i> , <i>Wangiella dermatitidis</i> , <i>Bipolaris</i> sp.
D. Eumycotic mycetoma	<i>Pseudoallescheria boydii</i> , <i>Madurella mycetomatis</i> , <i>M. grisea</i> , <i>Acremonium</i> spp., <i>Leptosphaeria senegalensis</i> , <i>Aspergillus nidulans</i>
E. Endemic fungal infections	<i>Blastomyces dermatitidis</i> , <i>Coccidioides immitis</i> , <i>Histoplasma capsulatum</i> , <i>Paracoccidioides braziliensis</i>
F. Infections with immunosuppression	<i>Cryptococcus neoformans</i> , <i>Trichosporon beigelii</i> , <i>Aspergillus</i> spp., <i>Zygomycetes</i> (<i>Rhizopus</i> spp. and <i>Mucor</i> spp.), <i>Fusarium</i> spp., <i>Blastoschizomyces capitatus</i> , <i>Penicillium marneffei</i>

Mycotic mycetoma

Mycetomas are swellings with draining sinuses and grains. They usually affect the feet, legs, or hands and begin with direct implantation of the causative organisms. The latter are either actinomycetes (actinomycotic mycetoma) or the true fungi (eumycotic mycetoma). About half of the cases of mycetoma are caused by true fungi, including the genera *Madurella*, *Leptosphaeria*, *Pseudallescheria*, *Acremonium*, plus several others. Initially, pain and discomfort develop at the implantation site, followed weeks or months later by induration, abscess development, granulomas, and draining sinuses. The lesions may extend to bone and cause severe bony destruction. Eumycotic mycetomas are rare in the United States, although those caused by *Pseudallescheria boydii* do occur there.

Specimens of exudates or biopsy material should be examined by the naked eye for the presence of grains. The latter can be Gram-stained and examined microscopically to differentiate actinomycotic from eumycotic mycetoma. The grains should be washed with saline containing antibacterial compounds and then cultured on Sabouraud's dextrose agar containing chloramphenicol and cycloheximide, as well as on media for bacterial and actinomycotic organisms. Identification of the organisms is based on gross colonial morphology, pigmentation, and mechanism of conidiogenesis. Treatment of eumycotic mycetoma is often unsatisfactory because the causative organisms generally show poor sensitivity to available antifungal agents. Amputation of an infected limb or surgical debridement of infected tissue may be necessary. Amphotericin B or azole antifungal drugs can be used if the particular fungal strain is sensitive. If not treated effectively, mycetomas may progress for years and produce marked tissue damage, deformity, and even death.

Systemic Mycoses with Cutaneous Manifestations

A number of deep fungal infections may produce cutaneous lesions as part of a disseminated disease process. In these infections, the portal of entry is usually the lung, with development of a pneumonia and spread to other organs. Dissemination is most likely to occur in patients with compromised host defenses. This process is different from that discussed in the last section wherein direct implantation into the skin or subcutaneous tissues is the usual mode of entry. The organisms causing systemic infections with spread to the skin are listed in Table 2; they include both the endemic fungi and opportunistic fungal organisms that infect immunosuppressed patients.

Glossary

Benthos Collection of organisms living on or within the sediments of water bodies.

Monophyletic A taxon or group of organisms that contains all extant descendants of a common ancestor.

Oxygenic photosynthesis Type of metabolism based on the coordinated action of two photosystems by means of which radiant energy is converted into chemical energy in the form of ATP, and reduction equivalents are obtained in the form of NADPH from the (photo)oxidation of water to free molecular oxygen.

Phycobilisome Macromolecular aggregates serving as antenna systems for the capture of light in photosynthesis, typical of cyanobacteria. They are composed of multimers of different phycobiliproteins and of linker polypeptides. Phycobiliproteins are polypeptides containing covalently bound open tetrapyrroles chromophores: the Phycobilins.

Plankton Collection of organisms living suspended in open waters. According to their function, oxygenic phototrophic organisms in the plankton are termed phytoplankton. By an unorthodox convention, planktonic organisms smaller than 2 µm in size are called picoplankton.

Sheath Structurally well defined, usually laminated, extracellular polysaccharide investment. The term is usually, but not exclusively, applied to those of filamentous cyanobacteria.

Trichome Row of vegetative cells in filamentous cyanobacteria, excluding the extracellular polysaccharide structures (sheaths). The term is complemented by 'filament', which includes both the trichome and the sheaths.

Defining Statement

Cyanobacteria are a monophyletic, ancient, morphologically diverse, and ecologically very important group of bacteria, most of which carry out water-oxidizing, oxygen-evolving, plant-like photosynthesis. With few exceptions, they synthesize chlorophyll *a* as the major photosynthetic pigment and phycobiliproteins as light-harvesting pigments. They typically fix CO₂ as the sole source of carbon using primarily the reductive pentose phosphate pathway.

Introduction

Cyanobacteria constitute a phylogenetically coherent group of evolutionarily ancient, morphologically diverse, and ecologically important bacteria. The majority of strains carry out oxygenic photosynthesis (water-oxidizing, oxygen-evolving, plant-like photosynthesis), although some intracellular symbionts have lost this ability. With few exceptions, they synthesize chlorophyll *a* as the major photosynthetic pigment and phycobiliproteins as light-harvesting pigments. They are able to grow using CO₂ as the sole source of carbon, which they fix using primarily the reductive pentose phosphate pathway. Their chemoorganotrophic potential is restricted to the mobilization of reserve polymers (mainly glycogen) during dark periods, although some strains are known to grow chemoorganotrophically in the dark at the expense of external sugars. As a group, they display some of the most sophisticated morphological differentiation among the bacteria, and many species are truly multicellular organisms. Two recently recognized bacterial groups, the *Melainobacteria* and *Sericytochromatia*, are their closest non-phototrophic relatives, which some consider members of a single phylum, rather than sister groups to the cyanobacteria. Cyanobacteria have left fossil remains as old as 2000–3500 million years, and they are believed to be ultimately responsible for the oxygenation of Earth's atmosphere. During their evolution, through an early symbiotic partnership, they gave rise to the plastids of algae and higher plants. Today cyanobacteria make a significant contribution to the global primary production of the oceans and are locally dominant primary producers in many extreme environments, such as hot and cold deserts, hot springs, and hypersaline environments. Their global biomass has been estimated to exceed 10¹⁵ g of wet biomass, most of which is accounted for by

[☆]*Change History*: March 2019. Tanya Soule and Ferran Garcia-Pichel updated the text and Further Reading. This is an update of Garcia-Pichel, F., 2009. Cyanobacteria. In: Schaechter, M. (Ed.), *Encyclopedia of Microbiology*, third ed. Academic Press. pp. 107–124. ISBN 9780123739445. doi:10.1016/B978-012373944-5.00250-9.

This article is an update of F. Garcia-Pichel, Cyanobacteria, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 107–124.

the marine unicellular genera *Prochlorococcus* and *Synechococcus*, the filamentous genus *Trichodesmium* (a circumtropical marine form), as well as the terrestrial *Microcoleus vaginatus* and *Chroococcidiopsis* sp. of barren lands. Blooms of cyanobacteria are important features in the ecology and management of many eutrophic fresh and brackish water bodies. The aerobic nitrogen-fixing capacity of some cyanobacteria makes them important players in the biogeochemical nitrogen cycle of tropical oceans, terrestrial environments, and in some agricultural lands. Because of their sometimes large size, their metabolism, and their ecological role, the cyanobacteria were long considered algae; even today it is not uncommon to refer to them as blue-green algae, especially in ecological studies.

With the possible exceptions of their capacity for facultative anoxygenic photosynthesis, and a group of symbionts of marine unicellular eukaryotes which lack crucial photosynthetic machinery, cyanobacteria in nature are known for being oxygenic photoautotrophs. It can be logically argued that after the evolutionary advent of oxygenic photosynthesis, the evolutionary history of cyanobacteria has been one geared toward optimizing and extending this metabolic capacity to an increasingly large number of habitats. This article provides an overview of the characteristics of their central metabolism and a necessarily limited impression of their diversity. Generalizations might, in the face of such diversity, easily become simplifications. Whenever they are made, the reader is reminded to bear this in mind.

Biodiversity: Taxonomy and Phylogeny

Taxonomy

For the newcomer, the taxonomy of cyanobacteria can easily become a nightmare; for the initiated, it is a persistent headache. Since in many cases cyanobacteria are indistinguishable ecologically from eukaryotic microalgae, they had been studied mostly by botanists. The epithets blue-green algae, Cyanophyceae, Cyanophyta, Myxophyceae, and Schizophyceae all apply to cyanobacteria. The botanical taxonomy was built using overwhelmingly morphological criteria based on observations from natural samples. There are actually two parallel botanical taxonomic treatments that exist. The 'Geitlerian' system, recognizing approximately 1300 species grouped in 145 genera and three orders, has been the most widely accepted, and has been the subject of more modern updates and modifications in the 'Anagnostidis/Komarek' system. The Drouet system represented an attempt to arbitrarily simplify the previous one, recognizing only 62 species in 24 genera. It was never judged appropriate by most taxonomists, but it was welcome by many biochemists and physiologists because of its ease of use. Many names of laboratory strains stem from Drouet's system, such as *Anacystis nidulans* (also known as *Synechococcus*), the *Escherichia coli* of cyanobacteria. The prokaryotic nature of cyanobacteria began to be fully recognized in the 1970s, when a taxonomic system based on the International Code of Nomenclature of Bacteria was initiated. This system relies on the study of cultured axenic strains, and it draws heavily on morphological and cytological information, but integrates some genetic and physiological traits as well. The maximal taxonomic resolution so far achieved in this system is at the genus level. The current state of the bacteriological taxonomy of the cyanobacteria is described in the second edition of the *Bergey's Manual of Determinative Bacteriology*. Agreement exists that eventually both systems should converge, but to date they coexist with their own advantages and shortcomings. One is left with the choice of either using a system that allows identification of species but is largely unreliable or using a more reliable system in which species are yet to be defined. To complicate the matter further, recently described nonphototrophic *Melainabacteria* and *Sericytochromatia* are placed within the phylum by some authors. Until the issue is resolved, and for the sake of clarity, we use the term cyanobacteria as a synonym of oxyphotobacteria. The diagnostic key to the cyanobacterial subsections (a taxon akin to Order), as given in the *Bergey's Manual*, is reproduced in Table 1. Most of the so-called form genera recognized within each subsection can be found in Fig. 1, in which they have been gathered according to some simple, mostly visual keys. This unavoidably abridged overview is not intended as a substitute for more thorough generic descriptions. In this article, for consistency, taxa not recognized in the *Bergey's Manual* appear in quotation marks, without intended detriment to their validity.

Table 1 Diagnostic key to the subsections of the cyanobacteria, according to the *Bergey's Manual of Determinative Bacteriology*

Subsection (traditional order)	Definitory criteria
Subsection I (Chroococcales)	Unicellular, nonfilamentous. Cells occurring singly or in aggregates. Cell division by binary fission in 1, 2, or 3 planes, symmetric or asymmetric, or by budding
Subsection II (Pleurocapsales)	Unicellular, nonfilamentous. Cells occurring singly or in aggregates. Reproduction by multiple fission without growth, yielding beaucytes (cells smaller than the parent cell), or by binary and multiple fission
Subsection III (Oscillatoriales)	Filamentous, binary fission in one plane, yielding uniseriate trichomes without true branching. No heterocysts or akinetes formed
Subsection IV (Nostocales)	Filamentous, division occurring only in one plane to yield uniseriate trichomes without true branching. Heterocysts formed when combined nitrogen is low
Subsection V (Stigonematales)	Filamentous, division occurring periodically or commonly in more than one plane, yielding multiserial trichomes, truly branched trichomes, or both. Heterocysts formed when combined nitrogen is low

Fig. 1 Genera (form genera) recognized in the *Bergey's Manual of Determinative Bacteriology* within each of the five subsections of the cyanobacteria. Genera have been arranged according to the most important (abridged) definitory criteria, and drawings are provided depicting their simplified morphological appearance and/or their life cycles.

Phylogeny

The most widely accepted reconstructions of cyanobacterial phylogeny are those based on comparisons of the 16S ribosomal RNA gene sequences. The salient traits of cyanobacterial ribosomal phylogeny have found support when other genes or multilocus analyses have been carried out, even with large sets of genes. Currently, several characteristics of cyanobacterial evolution can be inferred, and some taxonomic controversies have been settled. However, several apparent paradoxes have also been unveiled. Extreme caution should be exercised in the interpretations of phylogenetic trees of cyanobacteria because the nomenclatural chaos has already pervaded the molecular databases. In Fig. 2, a phylogenetic tree for the cyanobacterial radiation based on 16S ribosomal RNA gene sequences is presented, color coded to indicate the subsections of Fig. 1. The cyanobacteria are a diverse phylum, and studies support clearly the endosymbiotic theory for the origin of plant chloroplasts because they place plastids (from all eukaryotic algae and higher plants investigated) in a very diverse but monophyletic deep-branching cluster within the cyanobacterial radiation. However, the gross structure in the evolutionary history of extant cyanobacteria cannot be easily resolved; most of the cyanobacterial diversity probed seems to be due to an explosive radiation that took place early during their evolution. It seems clear that the current taxonomic treatment of the cyanobacteria diverges considerably from a natural system that reflects their evolutionary relationships. For example, subsections I, III, and II (orders Chroococcales, Oscillatoriales, and Pleurocapsales, respectively) do not find support in the trees as coherent units. The heterocystous cyanobacteria (subsections IV and V; Nostocales and Stigonematales,

Fig. 2 Phylogenetic tree of the cyanobacteria based on (complete) 16S ribosomal RNA sequences obtained from the Cydrasil open resource (<https://github.com/FGPLab/cydrasil>). Representative generic names have been added to many of the branches, but the list is not complete. Many morphogenera (i.e., *Leptolyngbya*) encompass a large diversity of phylogenetically unrelated clades, and the classification based on traditional subsections finds no support in phylogeny.

respectively) together form a monophyletic group with relatively low sequence divergence, but they are not monophyletic in their own right. Several other statistically well-supported groups of strains can be distinguished that may or may not correspond to currently defined taxa. With the advent of high-throughput sequencing, phylogenetic analyses using hundreds of protein-encoding genes are now possible. These phylogenies are largely congruent with those formed using 16S ribosomal RNA gene sequences. The picture that seems to emerge from these studies is that ecology and physiology are extremely important parameters to understanding the phylogenetic relationships of cyanobacteria and to achieving an evolutionarily coherent taxonomic system. Reaching this goal will necessitate continued efforts in the future.

Cytology and Morphogenesis

Cytology and Ultrastructure

Cyanobacterial cells range in width between 0.5 μm (e.g., *Prochlorococcus*) and 50–100 μm (e.g., some '*Chroococcus*' and some *Oscillatoria*); the modal size of the described species is significantly larger than that of most other bacteria and archaea ($\sim 4 \mu\text{m}$). In unicellular and colonial forms, cells may be spherical, bacilloid, or fusiform, and some strains present considerable pleiomorphism. Cells of filamentous cyanobacteria may range from discoid to barrel-shaped, and the trichomes often attain lengths on the order of millimeters. The filamentous genus *Stauria* has triradiate cells. Several types of cells may be present in morphologically complex cyanobacteria. The cells of most cyanobacteria are surrounded by a more or less-defined exopolysaccharide investment. In some species this may form a distinct, structured capsule or sheath, where the steric constrictions to cell growth imposed by the presence of mechanically strong capsules or sheaths may even dictate cellular shape (Fig. 3(p)). Several ultrastructural features are typical for cyanobacteria. The cell envelope is of a Gram-negative type but may attain a considerable thickness in the peptidoglycan layer (from several to 200 nm). Pores of different sizes, whether or not orderly arranged, perforate the cyanobacterial cell wall. Pore pits may allow close contact of the cytoplasmic membrane with the lipopolysaccharide outer membrane. The photosynthetic machinery of cyanobacteria resides on intracellular membranes (thylakoids). Each thylakoid consists of a double-unit membrane enclosing an

Fig. 3 Aspects of morphological diversity and morphogenetic processes in cyanobacteria. (a) Cocci of *Synechocystis* sp. strain PCC 6803, one of the most widely studied cyanobacteria. (b) Loosely aggregated colonies of a unicellular, extremely halotolerant cyanobacterium belonging to the Halothece cluster. (c) Filamentous *Anabaena* with intercalary heterocysts (hc). (d) Formation and extrusion of baecytes in unicellular colonial cyanobacteria after repeated rounds of division without growth (sequence from top to bottom). (e) *Chroococcus turgidus*, the largest unicellular cyanobacterium known with right cell undergoing fission. (f) Negative stain (India ink) of a colony of *Gloeotheca* sp., rendering the diffuse extracellular polysaccharide investments visible. (g) Cell differentiation in *Nostoc* showing vegetative barrel-shaped cells, heterocysts (hc), and akinetes (ak). (h) Field sample of *Gloeocapsa sanguinea*, with red-stained, well-structured extracellular polysaccharide sheaths. (i) A young filament of *Calothrix*, displaying a terminal heterocyst (hc) and a tapering trichome. (j) Filament of a *Pseudanabaena*-like, *Konvophoron*, with deep constrictions at cross walls and displaying trichome division by direct differentiation of mamillated (nipple-bearing) apical cells without mediation of necridia. (k) Trichome division in a *Lyngbya*-like (*Porphyrosiphon*) filamentous strain. The top-to-bottom sequence displays the formation of necridial cells (nc), their degradation, and the formation of two rounded apical cells (ac), different from the discoid intercalary cells and a leftover vestigial cell. (l) Helically coiled filament of *Spirulina*. (m) Heterocystous *Scytonema* showing the formation of false branches, as recently divided trichomes (see vestigial necridium, nc) break free from the sheath and continue to grow (not glide). (n) Asymmetric division (budding) in unicellular cyanobacteria of the genus *Chamaesiphon*. (o) Single trichome of *Microcoleus chthonoplastes*, with slight constrictions at the cross walls and bullet-shaped apical cell. (p) Pleiomorphy in a unicellular cyanobacterium, *Cyanophanon*, morphology being a result of steric constrictions to growth by their tough sheath. (q) Biseriate filament of *Stigonema*, with a true lateral branch.

Fig. 4 Cyanobacterial ultrastructure as seen by transmission electron microscopy. (a) Longitudinal section through a trichome of *Oscillatoria* 'lacus-solaris', showing thylakoid membranes parallel to the cell wall (TM), and large polyphosphate (PP) granules, as well as incipient septa (cross-walls). (b) Traversal section through a trichome of *Microcoleus chthonoplastes* showing radial, peripheral arrangement of thylakoids, a clear centrosome containing carboxysomes (polyhedral bodies, CS), and thylakoid membranes (TM). (c) Dividing *Synechocystis* strain PCC6803, showing clearly equatorial invagination of all tegumentary layers including exopolysaccharide (EPS) and cell wall (CW), and parallel sets of thylakoids membranes. (d) End cell in a *Nostoc pruniforme* trichome, with characteristic cyanophycin granules (CP), carboxysomes (CS), polyphosphate granules (PP), unordered arrangement of thylakoids, lipid droplets (LD), and septum or cross wall (S). The top insets show a detail of the tegumentary layers around the cross wall constrictions, with the plasma membrane (PM), and the peptidoglycan wall (PG) entering to form the septum, to the exclusion of the outer membrane (OM). The middle inset shows a thylakoid-rich region with thylakoid membranes (TM), intrathylakoidal space (IS), and the cytoplasm (C). The bottom inset shows a cyanophycin granule. (e) Outer regions in a *Oscillatoria* filament with, from right to left, exopolysaccharide (EPS) layer, cell wall (CW), a carboxysome (or polyhedral body, CS), rows of phycobilisomes (PBS) sitting on the cytoplasmic side of the thylakoid membranes, and a septum (S). Unpublished photomicrographs are from Mariona Hernández-Maríné (University of Barcelona, all but (c)) and Robert Roberson (Arizona State University, (c)), with permission.

intrathylakoidal space (Fig. 4(d)). Thylakoids may be arranged parallel to the cell membrane, radially, or in small disorderly stacks, depending on species (Fig. 4). They may be single or stacked, usually depending on illumination conditions. *Gloeobacter*, a representative of the most ancient cyanobacterial lineage, has no thylakoids and the photosynthetic apparatus resides in the plasma membrane. The phycobilisomes, used by most cyanobacteria as light-harvesting structures, can be distinguished in electron microscopic preparations as rows of particles ~50 nm in diameter on the cytoplasmic side of the thylakoids (Fig. 4(e)). These are obviously absent from chlorophyll *b*-containing, phycobiliprotein-lacking species (*Prochlorococcus*, *Prochloron*, and *Prochlorothrix*). A central electron-clear region in the cell, the nucleoplasm, or the centropasm, hosts the cellular DNA. Several intracellular nonmembrane-bound granules typically correspond to polymeric reserve materials, such as glycogen (polyglucose, usually present in the intrathylakoidal space), polyphosphate, poly- β -hydroxyalkanoates, and lipid droplets found in the cytoplasm proper, which are also common in other bacteria (Fig. 4). Cyanophycin (multi-L-arginyl-poly(L-aspartic acid)) is a cytoplasmic, exclusively cyanobacterial nitrogen reserve polymer. Carboxysomes (or polyhedral bodies) are commonly seen as membrane-bound intracellular inclusions, and they consist of accumulations of the enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (RubisCO), responsible for the initial carboxylation step in the Calvin cycle (see 'Dark reactions of photosynthesis: carbon fixation and uptake'), bound by a proteinaceous, viral capsid-like case (Fig. 4(e)). Gas vesicles are air-filled, cylindrical proteinaceous structures present in many planktonic species and in the dispersal stages of benthic forms; they provide buoyancy to the organisms. A large variety of ultrastructural inclusions of restricted occurrence are also known from particular species or strains.

Growth and Cell Division

Some strains cultured under optimal conditions display doubling times as short as several hours. In nature, one or more doublings per day is common in blooming planktonic populations, and cell divisions may be strongly governed by daily periodicity. Under

extreme conditions in the natural environment, net growth is sometimes best measured in units of percentage increase in biomass per year. Many cyanobacteria owe their ecological dominance and success not so much to the fast growth as to their ability to grow slowly and steadily in the face of environmental adversity. Slow growth rates may be an integral, genetically fixed part of the biology of many cyanobacteria. Cyanobacteria cells divide basically by fission, but the patterns of cell division, which vary, form the base of a morphological diversity unparalleled among prokaryotic organisms (Fig. 1). It is surprising that, because morphological complexity is such a unique cyanobacterial trademark in the bacterial world, our knowledge of the regulation of cell division patterns and morphogenetic implications at the biochemical and molecular level is virtually nonexistent. The extracellular slime layers or sheaths may contribute considerably to morphogenesis in some cyanobacteria by simply holding cells together after division in disorderly colonies (as in *Microcystis*), by holding filaments together into bundles (as in *Microcoleus*), or by allowing a localized extrusion of trichomes that result in 'false branching' (as in *Scytonema*; Fig. 3(m)).

Unicellular and Colonial Types

Cell division occurs here by inward growth of all tegumentary structures (cytoplasmic membrane, cell wall, outer membrane, and slime sheath), usually at an equatorial position (Fig. 4(c)). Asymmetrical division in one pole of unicells may result in small-sized daughter cells (budding; Fig. 3(n) and (p)), as in *Chamaesiphon*. A genetic capacity to alternate between two or three orthogonal division planes yields spatially ordered colonial forms, as in *Merismopedia* (planar colonies – two alternating division planes) or in *Myxosarcina* (cubical colonies – three alternating division planes). Multiple divisions occurring in the absence of cell growth result in the formation of a multiplicity of minute daughter cells (baeocytes) that eventually break free from the cell wall remains of the parental cell, as in all 'pleurocapsalean' (subsection III) cyanobacteria (Fig. 3(d)).

Filamentous Types

Repetitive division in a single plane without complete cell separation yields simple filamentous forms. The filamentous nature of some cyanobacteria may simply be due to this fact and may not necessarily imply a functional integration of the cells into a truly multicellular organism. In morphologically complex filamentous forms, however, the outer tegumentary layers may be continuous along the trichome. The formation of cross walls or septa may involve the invagination of the plasma membrane and the cell wall only, as has been shown in *Nostoc* (Fig. 4(d)), resulting in a continuous periplasm along the trichome. Septal junctions, analogous to metazoan gap junctions, then mediate intercellular molecular transfer by traversing the peptidoglycan of adjacent cells. In filamentous oscillatorian cyanobacteria, one or more tegumentary invaginations (future cross walls) may be initiated before cell division is completed. A widespread change of division plane in the cells along the trichome results in biseriate or multiserial trichomes (two or more rows of cells). A change in the plane of division occurring in a single cell and maintained for several rounds of fission results in true branching, as in *Stigonema* (Fig. 3(q)). In morphologically complex filamentous forms, cell division may be meristematic, occurring only in certain portions of the trichome (e.g., *Calothrix* and allied forms).

Multicellularity and Cell Differentiation

The magnitude of the morphological complexity evolved within the cyanobacterial radiation is exemplified by the achievement of multicellularity. The heterocystous group (subsections IV and V) and some oscillatorians are clearly not mere linear arrays of cells but truly multicellular organisms, possessing all the attributes required for such a distinction: supracellular structural elements, integrated behavioral responses to environmental stimuli, and distribution of labor through cell differentiation into distinct cellular types. The most common and important examples of cellular differentiation in cyanobacteria are reviewed below in detail, even though adaptation to particular environments have resulted in unique cell-types, such as the calcicytes of endolithic *Mastigocoleus testarum* or the diazocytes of *Trichodesmium*. Additionally, in many cases cyanobacteria form colonies or structurally organized macroscopic bodies (thalli in botanical terminology) that are quite large in size. Spherical colonies of *Nostoc* 'pruniiforme' exceeding 15 cm in diameter are known from the benthos of oligotrophic cold springs, but somewhat smaller, ordered arrangements of cells and filaments are common in other *Nostoc* and 'Aphanothece' species as well as in *Calothrix* and allied genera (e.g., 'Rivularia'). This metadifferentiation is seldom achieved in culture.

Hormogonia

Hormogonia (s. hormogonium) are short chains of ~5–25 cells formed and released from the parental, larger trichome. They serve a function in the dispersal of the organism, often in response to hormogonium-inducing factor secreted by plant host cells initiating symbiotic relationships with nitrogen-fixing cyanobacteria. Hormogonial cells may or may not be different in size and shape from vegetative cells. Detachment may involve the differentiation of a necridic cell separating the vegetative trichome from the hormogonium. Dispersal is aided by the expression of phenotypic traits, which may vary according to strains, such as gliding motility, development of gas vesicles, or change in surface hydrophobicity. Hormogonia eventually settle and dedifferentiate into a typical vegetative organism, which may subsequently differentiate into a heterocyst for a symbiotic relationship with a plant host. Transcriptomic analysis of cells differentiating into hormogonia in *Nostoc punctiforme* PCC 73102 resulted in differential expression of about 25% of the genes in the genome, many of which are of unknown function.

Heterocysts

Heterocysts (Fig. 3(c), (g), and (i)) are morphologically distinct cells that develop in response to a lack of combined nitrogen sources in the environment. The ability to develop heterocysts occurs without exception within a monophyletic group of filamentous cyanobacteria (heterocystous; subsections IV and V). They are usually larger than vegetative cells, develop thick tegumentary layers and intracellular hyaline buttons at the points of attachment to the vegetative cells, and display a pale coloration and reduced autofluorescence. As such, heterocysts are easy to recognize under the microscope. They may differentiate from end cells (terminal heterocysts, as in *Calothrix*) or from cells within the trichome (regularly spaced intercalary heterocysts, as in *Anabaena*, or lateral as in *Mastigocoleus*). Heterocysts are highly specialized in the fixation of dinitrogen under aerobic conditions. They represent a successful solution to the nontrivial problem of avoiding nitrogenase inactivation by free oxygen in oxygen-evolving organisms. Heterocyst biology has been relatively well studied at the biochemical and molecular levels. Heterocysts are the only cells that express *nif* (nitrogen fixation) genes and synthesize nitrogenase in heterocyst-forming cyanobacteria. Heterocysts do not evolve oxygen themselves (photosystem II (PSII) activity is absent or restricted) but a functional photosystem provides ATP. The source of reductant for nitrogen fixation is provided (as organic carbon) by the adjacent vegetative cells, which in turn obtain fixed nitrogen from the heterocyst in the form of amino acids (mostly glutamine). The heterocysts protect their nitrogenase from oxygen inactivation by maintaining reduced internal partial pressures of oxygen, a situation that is attained by means of increased rates of cellular respiration and, apparently, by restricting diffusive entry of oxygen from the environment as a result of their thick envelope. The developmental regulation of heterocysts is beginning to be understood at the genetic level. The autoregulated gene *hetR*, which is activated by a deficiency in combined nitrogen, plays a crucial role in the initiation of heterocyst development. On the other hand, the small peptide PatS inhibits heterocyst formation for the purpose of pattern formation to ensure that intercalary heterocysts are regularly spaced.

Akinetes

These nonmotile cells (Fig. 3(g)) are characterized by their enlarged size with respect to vegetative cells, their thick cell wall and additional tegumentary layers, and their high content of nitrogen reserves in the form of cyanophycin granules. They are formed exclusively by heterocystous filamentous cyanobacteria (but not by all) and they may differentiate *en masse* or at special locations within the filaments (usually close to or next to a heterocyst). Because akinetes are resistant to desiccation, low temperatures (including freeze-thaw cycling), and digestion in animal guts, they are considered resting stages in the life cycle, but they are fundamentally different from typical bacterial endospores in that they are not heat-resistant. Transcriptomic analysis of *Nostoc punctiforme* PCC 73102 cells differentiating into akinetes revealed that many of the down-regulated genes were associated with central metabolism, supporting their role as resting stages of the cell. In natural planktonic populations, massive akinete formation occurs at the end of the growth season. Germination of akinetes occurs when the environmental conditions become favorable for the growth of a vegetative filament. Genetic evidence suggest that the early regulatory process of akinete development and that of heterocysts has a common basis.

Terminal Hairs

These are multicellular differentiations occurring at the tips of trichomes in some members of the genus *Calothrix* and allied cyanobacteria (botanical family Rivularaceae). In response to nutrient limitation (e.g., phosphorous), the terminal parts of the trichome differentiate irreversibly into thin and long rows of narrow, almost colorless, vacuolated cells (hence the term hair). The hair is a site of preferential expression of cell surface-bound phosphatase activity.

Necridic Cells (Necridia)

Necridic cells occur in truly multicellular cyanobacteria (Fig. 3(n) and (k)). Necridic cells undergo a suicidal process (apoptosis), which begins with the loss of turgor and leakage of some cellular contents and continues with shrinkage and the separation of the cross walls (septa) from the adjoining cells. Eventually, the necridic cells will either rupture and disintegrate or remain as small, isolated vestigial cells. Cells adjacent to the necridium will usually develop morphologies typical for terminal (apical) cells. The formation of necridia may lead to the separation of one trichome into two (proliferation) or in the detachment of hormogonia from the vegetative filament. Most of the information about necridia is observational, and no studies have been performed to investigate the regulation of this morphogenetic mechanism.

Physiology and Metabolism

Cyanobacteria are photoautotrophic organisms *par excellence* and their metabolism is typically geared toward anabolic reactions. The basis of their metabolism is the conversion of radiant energy into chemically usable energy and the reduction of CO₂ into organic matter. The electron donor for the reduction of CO₂ is water, which is oxidized to molecular oxygen. The name of this type of metabolism is derived by the release of oxygen: oxygenic photosynthesis. It is exclusively carried out by organisms in the cyanobacterial radiation (cyanobacteria proper and the plastids of algae and plants).

Photosynthesis

In the light reactions of photosynthesis, radiant energy is captured and used to generate energy in the form of ATP and reduction equivalents in the form of nicotinamide adenine dinucleotide phosphate (NADPH). The light reactions of oxygenic photosynthesis are based on the coordinated action of (1) light-harvesting systems; (2) two chlorophyll *a*-containing, membrane-bound, multi-subunit enzymes known as photosystems; and (3) a series of soluble and membrane-bound electron-carrier proteins linking both photosystems (Fig. 5).

Light Harvesting

Light harvesting in most cyanobacteria (and in red algal plastids) is accomplished by highly ordered and structurally versatile supramolecular complexes known as phycobilisomes, which are primarily composed of phycobiliproteins. Phycobiliproteins are water-soluble proteinaceous pigments containing covalently bound, open-chain tetrapyrroles (phycobilines) as chromophores. Universal cyanobacterial phycobilines are the blue-colored allophycocyanin (absorbing maximally at a wavelength of 650 nm) and phycocyanin (maximum at 620 nm). Phycoerythrocyanin (maximum at 575 nm) and the red-colored phycoerythrin(s) (maxima vary from 495 to 560 nm) are also common. Multimeric disc-shaped phycobiliprotein complexes are stacked into either central cores or radially protruding rods (Fig. 5) to form a functional phycobilisome. The radiant energy absorbed by the phycobiliproteins along the rods is channeled vectorially (as excitation energy) toward the core region and from the core onto the reaction center of PSII or (partially) onto that of photosystem I. Phycobiliproteins are arranged orderly within the phycobilisome: the shorter the wavelength of maximum absorbance, the more peripheral their location. This allows for the centripetal channeling of excitation energy down a thermodynamically allowed sequence. In such a light-harvesting system, 300–800 phycobilin chromophores capture additional energy for ~50 Chl *a* molecules associated with PSII. In some strains, the phycobilin composition of phycobilisomes can be regulated to optimize the capture of photons according to the color of the available light, a phenomenon known as complementary chromatic adaptation. Excess light, however, can result in the production of toxic oxidative intermediates. The soluble orange carotenoid protein has been shown to play a critical role in photoprotection by initiating nonphotochemical quenching in the phycobilisome protein complex.

In addition to Chl *a*, some cyanobacteria use far-red (long-wavelength) chlorophylls. Chl *d* is the only other known cyanobacterial chlorophyll to participate in the reaction center. Chl *a* and Chl *d* both contain a similar tetrapyrrole structure with Mg^{2+} but differ in that Chl *a* absorbs maximally in the short-wavelength (visible) spectrum while Chl *d* absorbs in the long-wavelength spectrum (>700 nm). Chl *d* has been largely characterized in *Acaryochloris* where it serves as the predominant chlorophyll and facilitates light absorption at depths under phytoplankton surface layers which absorb most of the visible light energy. Chl *b*, Chl *c*, and Chl *f* serve as accessory antennae pigments that do not participate in the photosynthetic electron transport chain.

Fig. 5 Idealized organization of the photosynthetic components in and around cyanobacterial thylakoids and their associated activities. Multimeric complexes are indicated by labeled brackets. Abbreviations not explained in text are bound quinone (Q), plastoquinone (PQ), soluble electron carrier (SEC), ferredoxin (Fd), ferredoxin/NADP oxidoreductase (FNR). Thick black arrows indicate the direction of electron flow from water to NADPH; dashed arrow depicts the shortcut under cyclic phosphorylation conditions. Thin arrows depict either transformation of chemical reactants or the traffic of protons across the membrane. Modified from Bryant, D.A. (Ed.), 1996. *The Molecular Biology of Cyanobacteria*. Dordrecht: Kluwer, as cited, with permission.

Light Reactions of Photosynthesis

PSII, which contains a reaction center, known as P680, of very high basal reduction potential (+1 V), catalyzes the transfer of electrons from water to a bound quinone, with the production of O₂. The electrons then enter an electron transport chain involving successive redox reactions of a membrane-bound protein (plastoquinone), a membrane-bound protein complex (cytochrome *b₆f*), and one of the two intrathylakoidal soluble electron carrier proteins (cytochrome *c₅₃₃* or plastocyanin). An electrochemical gradient of protons is created across the thylakoid membrane in the process of electron transport. This is used by the thylakoidal f-type ATPase complex to generate ATP, the cell's energy currency. When excited, PSI, with a reaction center (known as P700) of intermediate reduction potential, catalyzes the reoxidation of reduced plastocyanin (or cytochrome *c₅₃₃*) with the concomitant reduction of ferredoxin (a soluble iron-sulfur protein) against a steep thermodynamic gradient. Reduced ferredoxin is used by ferredoxin: NADP⁺ oxidoreductase (an enzyme physically tethered to phycobilisomes, if present) to generate the NADPH necessary for the dark reactions. In short, the light-driven formation of ATP and NADPH has been achieved. Additionally, electron flow around PSI alone may also occur (cyclic electron transport). In this case, electrons flow from reduced ferredoxin directly to plastoquinone, through the cytochrome *b₆f* complex and plastocyanin, back to PSI and, with light, to oxidized ferredoxin, closing the cycle. The net effect of the cycle is the generation of energy but no reductant.

Dark Reactions of Photosynthesis: Carbon Fixation and Uptake

The reduction of CO₂ to organic matter (carbon fixation) occurs in all cyanobacteria, mainly through the reductive pentose phosphate (Calvin) cycle, in which the net formation of a triose from 3CO₂ is powered by ATP and NADPH formed in the light reactions. This cycle supplies important intermediates for anabolic reactions (triose, pentose, and hexosephosphate). Additional CO₂ may be fixed by phosphoenolpyruvate carboxylase, yielding C₄ acids, and by carbamyl phosphate synthetase/carbamylphosphate-ornithine carbamyl transferase, yielding citrulline and glutamate from glutamine, ornithine, and CO₂. The Calvin cycle is related to the catabolic (oxidative) pentose phosphate pathway, differing in two key enzymes that allow it to function anabolically. These are PRK (phosphoribulosekinase) and RubisCO, a very interesting enzyme and the most abundant protein on Earth. RubisCO is characterized by a low affinity for CO₂ and by possessing internal monooxygenase activity. This results in a competitive inhibition of carboxylation by free oxygen, a fact of obvious importance for oxygen-producing phototrophs. Under conditions of low CO₂ and high O₂ partial pressure, RubisCO catalyzes the oxidation of ribulose biphosphate to phosphoglycerate and phosphoglycolate. After dephosphorylation, glycolate is excreted by the cells in what seems to be a wasteful loss of carbon. Probably, to prevent conditions leading to such losses, cyanobacteria possess a carbon concentrating mechanism by which inorganic carbon, either as bicarbonate or as CO₂, is active at the expense of energy transported into the cell. This can result in intracellular concentrations of CO₂ 1000-fold higher than those outside the cells. A carbonic anhydrase-like enzyme keeps intracellular carbon in the form of bicarbonate to prevent leakage of CO₂. A carbonic anhydrase located within the carboxysomes (or polyhedral bodies, the site of RubisCO accumulation; Fig. 4) generates CO₂. With this system, a high CO₂ partial pressure is maintained locally in close proximity to the carboxylation sites of RubisCO, and the carboxylating activity of the enzyme is promoted.

Dark Metabolism

Energy generation in the dark occurs through aerobic respiration at the expense of glycogen accumulated during the light phase. Monomeric sugars are degraded using the oxidative pentose phosphate cycle. Most cyanobacteria are unique in that they have a non-traditional tricarboxylic acid cycle, in which 2-oxoglutarate is converted to succinate by 2-oxoglutarate decarboxylase and succinate semialdehyde dehydrogenase in the absence of α -ketoglutarate dehydrogenase, which has never been detected in any cyanobacterium. NADPH formed in sugar catabolism is fed to the membrane-bound electron transport chain at the level of plastoquinone. Terminal oxidases are cytochrome oxidases of the aa₃ type. The respiratory electron transport chain of cyanobacteria is housed in both the plasma and the thylakoidal membrane and it shares many functional components with photosynthetic electron transport. Approximately half of all cyanobacterial strains tested are obligate phototrophs, unable to use exogenous carbon sources aerobically. Some are photoheterotrophs, able to use some sugars as a carbon source, and some are facultative heterotrophs, able to grow, albeit slowly, at the expense of externally supplied sugars (usually only one) in the dark. All strains retain pigmentation and all components are necessary for photosynthesis under dark growth conditions. The lack of sugar transport systems has been heralded as one of the main reasons for the inability of many strains to use exogenous sugars while being able to respire endogenous glucose.

Cyanobacteria may also be subject to periods of anoxia, particularly in the dark (e.g., benthic forms thriving in sulfidogenic environments and biofilm or colony formers under diffusion limitations of O₂ supply). The only known electron acceptors alternative to oxygen for cyanobacterial chemoorganotrophy are internal organic compounds and elemental sulfur. Fermentation is not universal but is a relatively widespread ability in benthic and bloom-forming cyanobacteria. As in aerobic heterotrophy, fermentation occurs at the expense of endogenous sugars (usually glycogen but also sugar osmolytes such as trehalose or glucosylglycerol) accumulated in the light period. Some strains ferment, or even grow on, exogenous substrates anaerobically. Homolactic, heterolactic, homoacetate, and mixed-acid fermentation have all been described. There is evidence that the

Embsen–Meyerhof–Parnas glycolytic pathway, unoperative for aerobic respiration, is used in the fermentative degradation of sugars by cyanobacteria. Several cyanobacteria, notably *Lyngbya aestuarii*, produce copious amounts of hydrogen gas during the fermentation of photosynthate, a fact that makes them interesting for biotechnology. An *Oscillatoria* strain oxidizes endogenous carbohydrates largely to CO₂ in the presence of elemental sulfur with the concomitant production of sulfide. In other cyanobacteria, sulfur may be used as a sink for electrons, otherwise released as H₂, with or without concomitant modification of the fermentative products. A thermophilic *Synechococcus* reduces sulfate and thiosulfate to sulfide anaerobically in the dark. It is yet to be demonstrated that the reduction of sulfur is coupled to electron transport or energy generation.

Close Relatives of Cyanobacteria

The classes *Melainabacteria* and *Sericytochromatia* currently include only nonphototrophic members, and may in fact constitute a single phylum with cyanobacteria proper. *Melainabacteria* and *Sericytochromatia* sequences have been retrieved from anoxic environments such as the human gut, wastewater treatment facilities, subsurface groundwater, and a methane coal bed. Genomic data of these groups reveal that they lack the capacity for photosynthesis, but otherwise contain genes for fermentation, while some also appear capable of aerobic respiration. Also, unlike oxyphotobacteria, some of their genomes encode for flagellar proteins and some even exhibit a predatory lifestyle. Further study of these bacteria may provide interesting insight into the evolutionary history of cyanobacteria.

Secondary Metabolism

Cyanobacteria synthesize a variety of compounds that are not components of universal biochemical pathways, but have restricted distribution among taxa (secondary metabolites). These are thought to serve particular functions relevant to the survival of the strains in question, but their specific role has been deduced only in a few cases. Several important cyanobacterial metabolites are peptides synthesized in a nonribosomal setting by specific peptide synthetases. Compounds such as cyanobacterin (Fig. 6(c)), an herbicide produced by some *Scytonema* strains, potentially inhibit PSII of algae and cyanobacteria other than the producing strain, thus wiping out the competition. Scytonemin, a widespread indole alkaloid, is synthesized, excreted, and accumulated in large quantities in extracellular sheaths in response to ultraviolet (UV) radiation exposure, serving a sunscreen role (Fig. 6(h)). A similar sunscreen role has been proposed for a large variety of colorless mycosporine-like compounds (Fig. 6(f) and (g)). Triterpenoids of the hopane series found in thermophilic strains may stabilize the cell membranes under high temperatures. Other compounds display antibiotic activity, such as the antibacterial brominated biphenyls from *Oscillatoria 'chalybea'* (Fig. 6(k)) or the methoxytetradecanoic acid of *Lyngbya 'majuscula'* (Fig. 6(d)). However, for most cyanobacterial secondary metabolites identified, their biological function remains elusive. Such is the case for the volatile compounds 2-methylisoborneol and geosmin (Fig. 6(a) and (b), respectively), which are of common occurrence and responsible for the earthy smell and off-flavors in lakes harboring cyanobacterial blooms. A biological role for the notoriously famous cyanotoxins (Fig. 6(i) and (j)) is also difficult to define but some have suggested it provides them with a competitive advantage in response to grazing or resource competition. Another possibility for toxin synthesis is that production of complex secondary metabolites improves cell physiology by benefitting homeostasis, improving photosynthetic efficiencies, and accelerating growth rates. One study found that the toxin microcystin enhances the response to oxidative stress conditions in *Microcystis* by binding to proteins and decreasing their susceptibility to proteases. Among the bioactive compounds of unknown natural function, some have antioxidant, antineoplastic, antiviral, antiinflammatory, antimutagenic, ichthyotoxic, and dermatitis activities. Efforts to study the largely untapped cyanobacterial inventory of secondary metabolites and their biology has increased substantially due to their relevance to pharmaceutical research and public health. To this end, advances in genome sequencing efforts have accelerated the ability to use genome mining to discover novel natural products from cyanobacteria. In particular, *Lyngbya*, *Nostoc*, *Microcystis*, and *Haplosiphon* strains serve as rich repositories for discovery, as their genomes encode for hundreds of gene clusters related to natural product biosynthesis.

Metabolic Engineering

Metabolic engineering is the use of recombinant DNA technology to improve cellular activities. Most often metabolic engineering focuses on chemical manufacturing, biofuel production, or bioremediation. Cyanobacteria are ideal photosynthetic hosts for this purpose because there are many strains that are amenable to genetic manipulations. Classical genetic approaches to knock-in or knock-out genes have been used in a variety of cyanobacteria and are extensively reviewed elsewhere. More recent advances have taken advantage of clustered regularly interspaced short palindromic repeats (CRISPR) gene editing technology. Originally identified in bacteria as a defense mechanism against foreign DNA (e.g., viruses and mobile genetic elements), the Cas proteins associated with CRISPR sequences are RNA-guided DNA endonucleases capable of introducing blunt-ended double-strand breaks in specific target sequences. The CRISPR/Cas9 system was used successfully in *Synechococcus elongatus* PCC 7942 to improve yields of succinate by deleting the glucose-1-phosphate adenylyltransferase (*glgC*) gene in an effort to divert carbon away from glycogen and towards succinate. An alternative to CRISPR/Cas9 and Cas12a gene editing systems is CRISPR interference (CRISPRi) which utilizes an enzymatically inactive dead Cas9 (dCas9) to reduce the expression of genes that cannot be deleted. CRISPRi was first used in *Synechocystis* sp. PCC 6803 to demonstrate Green Fluorescent Protein (GFP) repression and has since been used successfully in

Fig. 6 Diversity of cyanobacterial secondary metabolites. (a) 2-methylisoborneol; (b) geosmin; (c) cyanobacterin; (d) 7-methoxy-4-tetradecanoic acid; (e) malynamide A; (f) and (g) mono- and bisubstituted mycosporines, respectively, where R stands for (amino) acidic moiety; (h) scytonemin; (i) anatoxin-a; (j) microcystin-YR; (k) a brominated phenyldiphenol.

Synechococcus sp. PCC 7002 to repress the phycobiliprotein complex and in the heterocyst-forming strain *Anabaena* PCC 7120 to regulate ammonium production.

Nutrition

Apart from liquid water, light, and inorganic nutrients, few additional requirements for growth are known in most cultivated strains. A requirement for vitamin B₁₂ has been demonstrated in some strains. Metabolic processes devoted to the provision of nutrients

may account for a significant part of the energy and reduction equivalents obtained in the light reactions of photosynthesis. Cyanobacteria possess specific uptake systems for nutrient assimilation. Orthophosphate can be taken up and stored intracellularly as polyphosphate (Fig. 4(a) and (d)), and the uptake may be aided by the action of surface-bound phosphatases, which release phosphate bound to organic molecules. The availability of phosphorous may often be the growth-limiting factor in natural freshwater populations. The production of siderophores (iron-chelating organic compounds) seems to be important in the assimilation of iron because Fe^{3+} ions, required for many of the enzymes involved in redox reactions, are very insoluble in water. The availability of iron may be growth limiting in oceanic planktonic species. Nitrogen-fixing cyanobacteria have complex sets of amino acid uptake systems, probably geared toward the recovery of leaked fixed nitrogen. In addition to uptake mechanisms, sulfur and nitrogen assimilation require additional reduction steps and are discussed separately in the following sections.

Nitrogen Assimilation

Among inorganic nutrients, nitrogen is of paramount importance as it accounts for ~10% of the dry weight of cyanobacterial cells. Nitrate (NO_3^-) and ammonium (NH_4^+) are virtually universal sources of nitrogen for cyanobacteria, but urea or other organic nitrogenous compounds can be used by some strains. In addition, many strains can fix gaseous dinitrogen (N_2). Plasma membrane-bound transport systems exist for both NO_3^- and NH_4^+ , whereas N_2 enters the cells by diffusion. Intracellular NO_3^- must be reduced to NH_4^+ . This is accomplished by the stepwise reduction to nitrite (catalyzed by nitrate reductase) and NH_4^+ (catalyzed by nitrite reductase), the reduction equivalents for both processes stemming from reduced ferredoxin. Ammonium (either taken up or endogenously generated) is assimilated by the glutamine synthetase/glutamate synthase enzyme system. The net action of this system is the formation of glutamate from α -ketoglutarate and NH_4^+ , with the expenditure of ATP and the oxidation of ferredoxin. Glutamate can donate its amino moiety to various precursors of central metabolism by the action of specific transaminases. Many, but not all, cyanobacteria are able to fix N_2 ; this is of great ecological significance because N_2 is ubiquitous in the environment. The process is carried out by the enzyme nitrogenase and is a costly one, involving the consumption of both ATP and reduction equivalents (supplied by ferredoxin). In addition, nitrogenase will also inevitably reduce protons to H_2 in what represents a wasteful decrease in efficiency.

Nitrogenase is inherently and irreversibly inactivated by O_2 . Several strategies have evolved in cyanobacteria to circumvent this problem. Some strains will only carry out N_2 fixation under anoxic conditions, but some will also do it in the presence of oxygen. Several strains have been shown to temporally restrict N_2 fixation to the dark period, thus decreasing the exposure of nitrogenase to photosynthetic oxygen. Strains belonging to the Nostocales and Stigonematales have evolved a specialized cell type (the heterocysts; see 'Heterocysts') in which nitrogen fixation is spatially separated from photosynthesis and protected from O_2 inactivation. Heterocystous strains display the highest specific rates of N_2 fixation among all cyanobacteria. However, some nonheterocystous cyanobacteria, such as *Trichodesmium*, are able to fix substantial, biogeochemically significant amounts of N_2 in the light. It is now known that nitrogen-fixation in *Trichodesmium* is spatially separated in specialized diazocyte cells and that oxygen concentrations are lowered by the Mehler reaction, in which the oxygen produced by PSII is reduced again after PSI. Some cyanobacteria that lack nitrogen fixation genes, like *Microcoleus vaginatus* of desert soils, enter into loose symbiotic relationships with heterotrophic diazotrophs in exchange for organics. The various mechanisms for nitrogen assimilation are tightly regulated so that the presence of less costly sources (NH_4^+) immediately inhibits NO_3^- (and NO_2^-) uptake, or N_2 fixation activity, and represses the expression of the enzymes involved in the reduction of alternative N_2 sources. In the same way, the presence of abundant NO_3^- represses the expression of nitrogenase genes and results in the halting of new heterocyst differentiation.

Sulfur Assimilation

Sulfate (SO_4^{2-}) is seemingly the universal source of sulfur for cyanobacterial cells, and it is only rarely growth limiting in the environment. Other sources of sulfur may be taken up alternatively, such as sulfate esters, sulfonate, hydrogen sulfide, and organic thiols. Sulfate is taken up by a SO_4^{2-} permease in an energy-dependent process, reduced to sulfide, and incorporated into cysteine. The cyanobacterial assimilatory sulfate reduction pathway is similar to that of other bacteria, involving the activation of sulfate by binding to ADP and the reduction of the sulfonucleotide to free sulfite using thioredoxin as a reducing agent. Sulfite is further reduced to sulfide by sulfite reductase using NADPH as an electron donor, and free sulfide is incorporated into cysteine by specific synthases. An oxidized sulfur source may also be a requirement for growth because, unlike other bacteria, cyanobacteria possess important structural components containing oxidized sulfur moieties: the sulfolipids of the photosynthetic membranes and, in some strains, the sulfate esters constituent of the extracellular polysaccharide sheaths.

Regulation

The regulation of cellular activities in cyanobacteria is similar in nature to that found in other prokaryotes, but photobiology plays a particularly important role. The presence and nature of the cyanobacterial photoreceptor systems (a cell's light meter) are well documented. Although specific photoreceptor molecules, some structurally similar to plant phytochromes, do exist, and some have been postulated as sensors of UV radiation, in many cases it is the indirect effect of light supply on the overall redox state of the cell that determines cellular responses. Small redox-sensitive proteins such as thioredoxin may act as general modulators of enzyme activity in carbon and nitrogen metabolism. The balance between carbon and nitrogen metabolism is typically sensed through the

levels of 2-oxoglutarate. Short-term (photo)responses can also be based on protein phosphorylation mechanisms, as seems to be the case for the process leading to the redistribution of captured energy between photosystems I and II (the so-called state transitions) or for the direct regulation of phosphoenolpyruvate carboxylase activities. By means of its multiple targeting, phosphorylation of a serine residue of P_{II} , a small regulatory protein, is thought to provide coordinated regulation of carbon and nitrogen metabolism. There is abundant evidence for light-mediated regulation of gene expression, leading to long-term responses, either to light intensity or to spectral composition. This is particularly true for genes encoding components of the photosynthetic apparatus, such as phycobiliproteins and PSII polypeptides. Some strains grown under light–dark cycles are capable of incorporating specific metabolic tasks into the swing of the cycle, relegating, for example, protein synthesis or nitrogen fixation to the dark periods. At least some of these daily patterns are maintained by an internal clock system, because the periodicity remains even in the absence of environmental stimuli. The core of this central clock, virtually universal among cyanobacteria, is an autophosphorylating enzyme, KaiC, that oscillates between nonphosphorylated and phosphorylated forms, and can modulate the expression of various central genes. Two-component (histidine kinase/response regulator) regulators seem to be common for signal transduction, particularly in responses to environmental stress or shock (cold, heat, salt, UV, and light), as well as for adaptation to some forms of nutritional limitation. Several histidine kinases with GAF-domains that function as photosensors or in phototaxis have been described in *Synechocystis*. Quorum sensing, using chemical signal molecules such as acyl-homoserine lactones, has been observed in some cyanobacteria to sense cell-population densities as part of biofilm formation. Quorum-sensing inhibition, through the production of inhibitory metabolites, has also been documented from cyanobacteria in a hypersaline system.

Noncoding RNAs (ncRNAs), also known as small RNAs (sRNAs), are known to play a role in post-transcriptional regulation by binding to complementary target mRNAs to affect their translation or stability. Cyanobacteria display a broad percentage in the amount of noncoding transcriptional start sites in a genome, from ~5% in *Prochlorococcus* to 26% in *Trichodesmium erythraeum*. ncRNAs are involved in a wide variety of functions, including regulation of photosynthesis and stress responses. In *Synechocystis* most of them have been shown to function as antisense transcripts which can have activating or repressive effects on gene expression.

Motility and Taxes

Flagellar proteins have only been identified in the nonphototrophic cyanobacteria while many unicellular and filamentous oxyphotobacteria display gliding motility. In some strains of oceanic marine *Synechococcus*, slow-swimming motility has also been described. Gliding is a movement across a solid or semisolid material in the absence of flagella or other conspicuous propulsion mechanisms and without apparent change in cellular (or trichome) shape. Gliding is typically accompanied by the secretion of slime and in filamentous cyanobacteria this polysaccharide layer may provide a suitable surface for motility. In *Nostoc* hormogonia and *Synechocystis*, gliding motility is facilitated by type IV pili in an ATP-dependent manner. In filamentous forms, rotation of the trichomes along their main axes often occurs while gliding. The structural involvement of a Ca^{2+} -binding glycoprotein, oscillin, in cyanobacterial gliding has been determined; it forms supracellular helical fibrils in the outermost surface of the trichomes. Gliding motility may be displayed only transiently (i.e., in hormogonia or in baeocytes but not in vegetative cells). Photosensory and chemosensory systems, allowing the organisms to respond to temporal or spatial environmental gradients, are tightly coupled to motility, resulting in the so-called tactic behavior. Positive tactic responses to chemical species (chemotaxis) such as bicarbonate, nitrate, and plant exudates in symbiotic species have been shown in cyanobacteria (i.e., they move up chemical gradients of concentration of those substances). Terrestrial cyanobacteria are the only microorganisms shown to have tactic responses to water. Even halotaxis, movement towards optimal salinity, has been reported in cyanobacteria from an intertidal hypersaline microbial mat. All motile cyanobacteria display phototactic behavior so that the populations are able to seek optimally illuminated areas. Both positive and negative phototaxis systems exist, to achieve both optimal illumination as well as avoid damaging UV radiation. Like other bacteria, cyanobacteria usually respond by stopping and changing the direction of movement (reversing) upon crossing a sharp boundary in light intensity (photophobic response); however, some are also capable of perceiving the angular direction of the light and respond by steering toward or away from the direction of the incoming light. Spherical cells of *Synechocystis* act as microlenses to sense light in what has been described as the “world’s smallest and oldest example of a camera eye”. In this analogy the cell acts as a spherical microlens and the cell membrane, which contains a variety of photoreceptor proteins, acts as the retina, providing vision for the phototactic response. This capacity (known as true phototaxis) has no parallel in any other prokaryote.

Molecular Genetics

Genomes

Cyanobacterial genomes are typically prokaryotic in nature and located in the centropilasm. Most genomes are circular but linear chromosomes have been observed in *Cyanothece*. Many cyanobacteria are polyploid or oligoploid, with 53 chromosome copies per cell in *Synechocystis* sp. PCC 6803 and as few as two copies in *Synechococcus elongatus* PCC 7942. The genomes of free-living cyanobacteria vary widely in GC base composition from 32% to 71%, a range comparable to that spanned by all bacteria. They also vary in size, approximately correlating with morphological complexity, from 1.6 to 14×10^6 bp (base pairs) (~1700–10,000 genes). The smallest cyanobacterial genomes are thus similar in size to those of most bacteria, whereas the

largest ones are in the range of eukaryotic fungal genomes. Symbiotic cyanelles and plastids have retained only 0.13×10^6 bp in their genomes. To date, more than 300 cyanobacterial genomes have been fully sequenced, including many strains of *Synechococcus* and *Prochlorococcus*. Based on an analysis of 58 cyanobacteria, a core cyanobacterial genome of 559 genes has been suggested, along with three signature genes for thermophilic and 57 signature genes for heterocystous cyanobacteria. The DNA of cyanobacteria is subject to very extensive modification, and DNA methylation patterns in nitrogen starvation and nitrogen recovery over twelve generations in *Synechocystis* suggest that transgenerational epigenetic processes exist in cyanobacteria. The presence of widespread, highly iterated short palindromic sequences is a trait shared by many, but not all, cyanobacterial genomes and CRISPR sites are also common. Genomic rearrangements involving deletion, operon fusion, and translocation events are known to occur during heterocyst differentiation. Plasmids or extrachromosomal replicons are commonly encountered (some as large as 1.5×10^5 bp), but they are usually cryptic and do not appear to be responsible for antibiotic resistance phenotypes, as in other bacteria. Some are known to bear genes encoding for isozymes involved in assimilatory sulfate reduction.

Gene Transfer

There is evidence from phylogenetic comparisons that horizontal genetic exchange among related cyanobacteria has played a significant role in their evolution. Nevertheless, the mechanisms leading to genetic exchange are difficult to pinpoint. Despite the abundance and spread of cyanobacterial plasmids, natural conjugation among cyanobacteria has not been reported. The same is true for viral transduction, despite the wealth of cyanophages described in the laboratory and from natural populations, some clearly carrying cyanobacterial genes in their genomes. Some strains are naturally highly competent for taking up foreign DNA, but unaided transformation seems to be restricted to some unicellular strains of the genera *Synechococcus* and *Synechocystis*. The latter of which has been shown to use type IV pili and DNA-binding proteins to enhance transformation efficiency. In the laboratory only transformation (or electroporation) and conjugation are used to transfer DNA into cyanobacterial cells. Even though transformation has been used on some filamentous strains, most gene transfer of these strains in the laboratory is done by conjugation.

Gene Expression

Control of gene expression at the level of transcription seems to play a significant role in the adaptation to changing environmental conditions. Cyanobacteria possess a transcriptional apparatus of unique characteristics among bacteria. The cyanobacterial DNA-dependent RNA polymerase is structurally different from that of the common bacterial type, possessing an additional subunit in its core, and several sigma factors (polypeptides, whose association with the core of the polymerase is needed for effective initiation of transcription) have been identified. It has been shown that a 'principal' sigma factor is commonly present under normal growth conditions, *sigA* in *Synechocystis*, whereas alternative factors are temporarily expressed upon, for example, a change to nitrogen-limiting conditions. Because cyanobacterial promoters lack some of the distal consensus sequences of other bacteria, it has been hypothesized that regulation of transcription may often be activated by accessory factors other than sigma factors. Small noncoding RNA transcriptional regulatory elements (see 'Regulation') appear to be widespread among the cyanobacteria, with documented studies in unicellular, filamentous, and heterocystous types. Examples of sRNAs/ncRNAs involved in regulation include *IsaR1* and *NsiR4*, which are involved in iron and nitrogen depletion, respectively, and *PsrR1* which is involved in the high light stress response.

Systems Biology

Systems biology approaches to studying cyanobacteria have generated a variety of 'omics' datasets, most of which are focused on genomics, transcriptomics, proteomics, and metabolomics. The sequencing of over 300 cyanobacterial genomes has expanded the capabilities of applying these approaches to better understand these complex biological systems. Early studies relied on the development of DNA microarrays which were limited to only a handful of cyanobacteria. More recent approaches utilize RNA-Seq (RNA Sequencing), which provides whole-transcriptomic analysis using next-generation sequencing. RNA-Seq also offers annotation of transcriptional start sites, promoter regions, and identification of new genes, particularly noncoding RNAs. Furthermore, RNA-Seq can be applied to any sequenced organism, although current datasets are mainly from *Synechocystis* sp. PCC 6803. Proteomics began with the use of two-dimensional gel electrophoresis with peptide identification through mass spectrometry and has now advanced into gel-free approaches such as selected reaction monitoring (SRM), which allows precise quantification of targeted proteins. SRM has been applied to the *Synechocystis* sp. PCC 6803 proteome to quantify proteins controlled by the transcriptional factor *SufR* and the noncoding RNA *IsaR1*. Advanced proteomic methods also offer the advantage of identification of protein modifications such as phosphorylation and glutathionylation. Metabolomics uses gas or liquid chromatography in combination with mass spectrometry to quantify cellular metabolites. This method is currently capable of providing quantitative analysis of about 100 cyanobacterial metabolites. An extension of metabolomics is the measurement of flux (fluxomics) using stable isotopes such as ^{13}C . This type of analysis can reveal candidate enzymes and pathways for targeting in order to optimize growth or output under specific growth conditions. For example, ^{13}C -flux experiments using *Synechococcus* sp. PCC 7002 cells revealed changes in cell composition in response to different light regimes.

Ecology and Adaptations

The range of environmental conditions under which cyanobacteria can develop is impressively wide, and equally wide is the variety of ecological adaptations they display. One can find cyanobacteria as an important part of the primary producer community in almost any habitat in which light penetrates. Thermophilic cyanobacteria mainly of the genera *Synechococcus* and *Thermosynechococcus* can grow up to temperatures of 73°C in hot springs, which is the upper temperature limit for photosynthesis. Cyanobacteria can also develop stable populations in polar soils, rocks, and ponds in which temperatures rarely exceed a few degrees Celsius. In fact, low-temperature ecotypes can be differentiated from warmer temperature strains by comparing ribosomal sequences. Some forms thrive in rain or snow-melt puddles of extremely low inorganic solute concentrations, and some halotolerant types grow in NaCl-saturated brines. Halophilic cyanobacteria, which are often nonheterocystous strains, can be found in saltern evaporation ponds at salinities above 200 g L⁻¹. One of the major strategies for coping with salt stress is to accumulate compatible solutes such as sucrose, trehalose, glucosylglycerol, and glycine betaine. It was even shown that the salt tolerance of cyanobacteria could be predicted by which compatible solutes were encoded for in their genomes, with sucrose and trehalose more common in freshwater strains and glycine betaine common in hypersaline strains. Some cyanobacteria thrive in caves, deep in lakes, and in coastal areas, where light is extremely dim, while some terrestrial forms develop permanent populations in mountainous tropical areas exposed to the highest levels of solar radiation found on Earth. Many terrestrial cyanobacteria are desiccation resistant, and they withstand freeze-thaw cycles. Benthic marine cyanobacteria flourish under supersaturated oxygen, often exceeding 1 atm in partial pressure during daytime, but they are exposed to anoxia at night. It is common that more than one of these extreme conditions coincide in one particular habitat. One of the most conspicuous limitations to the development of cyanobacteria seems to be acidity: although many are known from alkali lakes, no *bona fide* reports of growth below pH 4.5 exist. The ecological success of cyanobacteria in many of these extreme habitats is often a result of their metabolic resilience in the face of environmental insults rather than a consequence of sustained growth. A few environmentally relevant cyanobacterial habitats are discussed in the following sections.

Marine Plankton

With the possible exception of polar areas, morphologically simple cyanobacteria of small size (0.5–2 µm) inhabit in large numbers in the upper zone of the oceans where light penetrates. These are referred to as picoplankton, and consist of two phenotypically distinct but phylogenetically related groups (Fig. 2): the open-ocean marine *Synechococcus* and *Prochlorococcus*. Population sizes typically range between 10⁴ and 10⁵ cells per ml for both types. The global biomass of picoplankton must be on the order of 1–2 billion metric tons (1600 × 10¹² g). This sheer size indicates their ecological importance. It has been calculated that as little as 11% and as much as 50% of the primary production of nonpolar open ocean regions is due to their activity. This group has developed interesting adaptations to the light field of clear oligotrophic (nutrient-poor) waters: their light-harvesting complexes have differentiated to match the predominantly blue light available. *Synechococcus* cells synthesize a special kind of bilin chromophore, phycourobilin, absorbing maximally at 490–500 nm, thus increasing the ability of cells to use blue light. Evolutionary pressure of a similar nature has probably resulted in the virtual loss of phycobiliprotein-based light harvesting in *Prochlorococcus* and the evolution of antenna mechanisms based on (divinyl) chlorophylls (*a* and *b*), which are optimally suited to capture blue light. The life strategy of picoplankton populations is based on fast growth, with cells often displaying several doublings per day. Grazing pressure and viral infection seem to be the major factors controlling population sizes. The comparatively small size of picoplankton genomes, the absence of nitrogen-fixing capacity and of some reserve polymers such as phycocyanin, and the lack of mechanisms to withstand small concentrations of toxic metals such as copper may be the result of reductionist evolutionary pressures favoring fast growth. Their small size (large surface to volume ratio) may provide selective advantage in nutrient-poor environments. Furthermore, *Prochlorococcus* is capable of utilizing non-phosphorous lipids such as phosphonates (organic carbon-phosphorous compounds) in the oceans. Phenotypic and genetic variation exists within the picoplanktonic cyanobacteria, resulting in strains that diverge in light and temperature optima for growth: high- and low-light-loving strains of *Prochlorococcus* have been described as well as mesophilic and moderately psychrophilic strains of *Synechococcus*. Double-stranded DNA cyanobacterial myoviruses abundant in marine environments have been studied in both *Synechococcus* and *Prochlorococcus*, for which there appears to be a ‘cyanophage core genome’ that exists across at least 16 cyanophage genomes. Some of these cyanophage genomes carry genes for the light reactions of photosynthesis, the pentose phosphate pathway, and phosphorous acquisition, enhancing these processes in marine cyanobacteria.

The intensely red (phycocerythrin-containing) oscillatorian cyanobacteria of the genus *Trichodesmium*, which typically occur as bundles of filaments in the wild, constitute the second most important group of marine planktonic cyanobacteria, with a global biomass estimated at 100 × 10¹² g. They are inhabitants of oligotrophic tropical open ocean regions worldwide, in which they may form blooms that can be detected as surface accumulations with the naked eye. They are responsible for much of the global oceanic nitrogen fixation, and this nitrogen-fixing capacity is a key factor of their ecological success. The particular adaptations that allow nonheterocystous *Trichodesmium* filaments to fix nitrogen in the light involve specialized diazocyte cells and reduction of oxygen after PSI (see ‘Nitrogen assimilation’). They also contain large amounts of gas vesicles that provide positive buoyancy to the filaments so that they remain in the upper wind-mixed layers of the ocean. *Trichodesmium* gas vesicles are among the sturdiest in prokaryotes, apparently so that they can withstand the large hydrostatic pressures experienced upon mixing of the deep mixed layers of open-ocean waters. Large, unicellular populations of ‘*Crocosphaera*’ fix nitrogen at night and also contribute significantly to the inputs of new nitrogen in the oceans along with *Trichodesmium*.

Freshwater Plankton

Although not a major component of the global biomass (with only some 30×10^{12} g), a large variety of cyanobacteria are found as components of the phytoplankton of fresh waters, and are particularly prominent or dominant under conditions of nutrient eutrophication. In eutrophic lakes and man-made reservoirs (and in enclosed brackish water basins such as the Baltic), the formation of cyanobacterial blooms results in serious water quality problems regarding not only the degradation of the recreation potential, musty odors, and off-flavors that are associated with bloom development, but also the likelihood of fish kills due to anoxic events after bloom decay and the production and release of cyanobacterial toxins. These are known to have caused animal and, in extreme cases, human deaths. Bloom-associated health effects reach beyond local environmental agencies and are being considered in rulings of the World Health Organization. Gas-vacuolated species in the heterocystous genera *Anabaena*, *Nodularia*, '*Gloeotrichia*', and *Aphanizomenon*, as well as in the nonheterocystous genera *Oscillatoria* and particularly *Microcystis*, are notoriously responsible for bloom formation and for reported cases of intoxication.

Terrestrial Environments

Desiccation-resistant terrestrial cyanobacteria have widespread occurrence. They may be found growing on bare surfaces (rocks, trees, buildings, and soils) or several millimeters within more or less soft diaphanous substrates (soils, sandstone, and limestone). Some species actively bore into the rock substrate. The availability of liquid water, in the form of rain or dew, determines the potential spurts of growth of cyanobacteria in the terrestrial environment. Growth of terrestrial cyanobacteria can be fast and luxurious in tropical humid climates, but in most other regions it is usually only intermittent. Their life strategy is usually one of slow growth and enhanced resilience. Adaptations to this environment are directed to withstand both desiccation (e.g., by abundant exopolysaccharide production) and exposure to solar radiation under inactive conditions (by the synthesis of sunscreen pigments). The negatively charged polysaccharides surrounding the cells also aids in sequestering metal cations necessary for growth. The exclusion of higher plant vegetation by climatic rigors determines the relative importance of cyanobacteria in terrestrial habitats. Thus, extensive endolithic cyanobacterial communities (accounting for as much as 140×10^{12} g of biomass globally), usually dominated by members of the genus *Chroococcidiopsis*, have been described from tropical, desert, and polar environments. These communities play a significant role in rock erosion processes, and their actions have become a concern for the preservation of stone monuments. Edaphic (soil dwelling) cyanobacteria are also distributed worldwide, and represent one of the largest global reservoirs of biomass, with some 540×10^{12} g. Sheathed oscillatorian forms such as *M. 'vaginatus'*, possibly the most common and widespread, along with heterocystous ones (*Nostoc* and *Scytonema*), are major ecological players in arid and semiarid regions, both hot and cold. Edaphic cyanobacteria in the so-called biological soil crusts contribute significantly to the physical stability and fertility of arid soils worldwide.

Sulfidogenic Environments

Hydrogen sulfide interferes with PSII and acts as a potent inhibitor of oxygenic photosynthesis. Many marine and freshwater habitats, such as hot springs, marine littoral sediments, and the deep water of lakes, may contain significant amounts of free sulfide. Cyanobacteria develop the most conspicuous populations of oxygenic phototrophs in such environments when sufficient light is available. Specific adaptations to these habitats include the ability to express sulfide-resistant forms of PSII so that oxygenic photosynthesis can proceed even in the presence of sulfide (e.g., in the marine benthic *Microcoleus 'chthonoplastes'* and in some hot spring and freshwater oscillatorians) and also an ability to perform anoxygenic photosynthesis using hydrogen sulfide as a source of electrons instead of water (e.g., in *Oscillatoria 'limnetica'* and members of the 'Halothece' cluster from hypersaline waters, *Oscillatoria 'amphigranulata'* from hot springs, or *Pseudanabaena* sp. from hardwater lakes). Many strains display both adaptations simultaneously. The ability to use sulfide as an electron donor has been traced to the inducible expression of a soluble enzyme, sulfide:quinone oxidoreductase, which can transfer electrons from sulfide to plastoquinone, thus allowing the noncycling function of PSI (Fig. 5) with the formation of both ATP and NADPH. Although some strains in culture show continued growth using anoxygenic photosynthesis alone, they cannot compete successfully for sulfide with phototrophic sulfur bacteria in the environment. It is thought that cyanobacteria use anoxygenic photosynthesis as a means for sulfide detoxification. Indeed, many use anoxygenic photosynthesis only temporarily, until local concentrations of sulfide are sufficiently low and (sulfide-resistant) oxygenic photosynthesis can begin.

Symbioses

Although they show an apparent lack of taste for sexual matters, cyanobacteria have displayed a considerable evolutionary promiscuity, entering into intimate symbiotic associations with various unrelated organisms. The list of cyanobacterial symbioses is large. There is also a large variation in the degree of independence maintained by the cyanobacterial partners. In some cases, the distinction of two organisms may no longer be possible because cyanobacteria lose their typical appearance and a large portion of their genomes to their hosts. This is obviously the case in higher plant and eukaryotic algal plastids, in which massive loss of genes to the eukaryotic nucleus has occurred. Cyanelles (plastid-like endosymbionts of eukaryotic protists) have retained the peptidoglycan and phycobilines, but their identity loss is substantial as well. These cases are no longer considered symbioses. At the other end of the spectrum, loose but mutualistic relationships between cyanobacteria and other bacteria or fungi (the so-called consortia) have been

described, but these are not considered here. Well-known cyanobacterial symbioses can be functionally divided into those formed by heterocystous cyanobacteria, in which the main contribution of the cyanobacterial partner is the supply of fixed nitrogen, and those formed by nonheterocystous types, in which their contribution is often the supply of fixed carbon. According to the degree of intimacy attained, they can be classified into intracellular (in which cyanobacterial cells are found within cells of other organisms) and extracellular (in which cyanobacterial cells are located within the tissues but outside the cells of other organisms). The most common extracellular symbioses of nonheterocystous cyanobacteria (involving the unicellular genera *Chroococcidiopsis*, *Gloeocapsa*, '*Chroococcus*', and *Gloeotheca*) are in the form of cyanolichens. *Prochloron*, *Acaryochloris*, and large-celled *Synechocystis* are known from extracellular symbioses with ascidians in tropical or subtropical marine waters. Extracellular symbioses of *Pseudanabaena*-like '*Konvophoron*' occur in Mediterranean sponges. Filamentous *Phormidium* has been reported in symbioses with some green algae. Intracellular symbioses of nonheterocystous cyanobacteria are known from tropical sponges ('*Aphanocapsa*', *Oscillatoria*, *Synechocystis*, and *Prochloron*), from green algae (*Phormidium*), and from dinoflagellates (*Synechocystis* and *Synechococcus*). Heterocystous cyanobacteria in the genus *Nostoc* are known to form extracellular symbioses with liverworts and higher plants (Cycads and duckweed). *Anabaena* enters into symbiosis with water ferns of the genus *Azolla*. Cyanolichens are known to contain members of the heterocystous genera *Nostoc*, *Calothrix*, *Scytonema*, *Stigonema*, and *Fischerella* as photobionts. Intracellular symbioses of heterocystous cyanobacteria occur in oceanic diatoms of the genera *Hemiaulus* and *Rhizosolenia* (cyanobacterial genus '*Richelia*') and in *Trifolium* (clover) with *Nostoc*. *Nostoc* also enters into intracellular symbioses with the terrestrial nonlichenic fungus *Geosiphon* pyriforme.

Fossil Record and Evolutionary History

The fossil record of cyanobacteria contains the oldest entries that can be confidently assigned to any extant group of organisms. Excellently preserved microfossils, 1000 million years old, bear virtually indisputable cyanobacterial morphologies. Fossil cyanobacteria showing considerable morphological diversification have been described dating back at least 2500 million years, which is also corroborated by phylogenetic analyses of scytonemin genes, dating heterocyst-producing clades as early as 2450 million years. Additionally, filamentous bacteria of putative cyanobacteria identity are known from as far back as 3500 million years. In fact, it has been suggested that cyanobacteria have evolved only very slowly in the intervening time because present and past morphologies are very similar. In view of the biochemical and physiological diversity of adaptations that particular cyanobacteria display, some doubts may be cast on such a perception. Lipid biomarkers, such as 2-methylhopanoids preserved in rocks as old as 2700 million years, have been used to identify cyanobacteria in the rock record. However, the use of 2-methylhopanoids to date cyanobacteria must be used with caution since genes involved with 2-methylhopanoid biosynthesis are found in other prokaryotes. The fossil record of the Archaean and Proterozoic Eons (before 500 million years ago) offers strong evidence not only for the presence of cyanobacteria but also for a type of environment they must have inhabited: the sedimentary environment of shallow coastal waters. This is recorded in the abundant organosedimentary laminated macrofossils known as stromatolites or microbialites, which became geographically restricted in the Phanerozoic. Stromatolites are analogous to present-day cyanobacterial mats, benthic compact assemblages built by cyanobacteria in extreme environments, and have provided evidence for the sustained importance of photoresponses in the ecology of cyanobacteria in the form of 'heliotropic' accretions. Precambrian fossil microboring on marine carbonaceous substrates reveals the sustained role of cyanobacteria in small-scale geomorphological processes. Fossil evidence for the presence of eukaryotic algae is also quite old, perhaps as much as 2000 million years, which is in agreement with the early offshoot of the plastidic line of evolution suggested by phylogenetic reconstructions. The oldest fossil evidence for terrestrial cyanobacteria, in the form of *Gloeocapsa*-like cells symbiont in lichens, is comparatively young (400 million years). Thus, cyanobacteria have inhabited Earth for a long time and survived through geological periods of environmental conditions very different from those reigning today. In the early days of cyanobacterial evolution, high fluxes of short-wavelength UV radiation penetrated the oxygen- and ozone-free, carbon dioxide-rich atmosphere. Oceans were shallow and rich in reduced iron and poor in sulfate and nitrate. In fact, it is thought that oxygenic photosynthesis was the ultimate cause, regulated by geological events of carbon burial, for the change in most of these parameters, including the late Proterozoic oxygenation of the atmosphere.

Phylogenetic reconstructions suggest that the genes for photosynthesis were acquired late in cyanobacterial evolution and that the nonphototrophic *Melainobacteria* and *Sericytochromatia* represent the ancestral state of this phylum. The hypothesis has been presented that genetic fusions between different oxygenic phototrophs may have led to the evolution of a two-photosystem photosynthetic apparatus in the predecessor of cyanobacteria, perhaps using iron as an electron donor. Comparative biochemistry of the proteins in the different photosystems suggests homologies between PSII of cyanobacteria and the photosystems of purple sulfur bacteria, as well as between PSI and the photosystems of green sulfur bacteria. The evolutionary lowering of the basal potential of the type II photosystem, allowing the retrieval of electrons directly from water, would have supposed the tapping of a virtually unlimited and ubiquitous source of electrons for CO₂ reduction. This would have provided the first oxyphotobacterium with a wide range of potential niches and possibly enabling an early explosive radiation of particular adaptations.

Commercial Use and Applications

The commercial use of cyanobacteria has long been sought for but in most cases has not reached the production stage. Procedures and modified strains have been devised, for example, for the industrial production of amino acids, ammonia, and for the control of

mosquito larvae using genetically engineered strains that produce *Bacillus* toxins. The main commercial use of cyanobacteria is for the production of bulk biomass for human consumption, a practice that has a long history in traditional cultures. Natural blooms of *Arthrospira* (previously assigned to *Spirulina*) were collected, sun-dried, and cut into cakes for human consumption in preHispanic Mexico; this 'tecuitlatl' of the Aztecs was highly regarded and commercialized at that time. A very similar procedure is used today to manufacture 'Dihé' cakes by the Kanembu tribeswomen from the shores of Lake Chad. Indeed, dried *Arthrospira* contains 60%–70% protein. Today, it is also produced commercially in outdoor man-made facilities and commercialized under the trade name 'Spirulina' for the health-food market as a protein-rich, low-calorie, cholesterol-free, vitamin-loaded food supplement. Due to the cult that has developed regarding this form of food supplement, blooms of other species ('Aphanizomenon', traditionally not consumed and strains of which are known to contain toxins) are also being commercially sold. *Nostoc commune*, a terrestrial cyanobacterium, is considered a delicacy and has been collected and marketed for centuries in China. Given the central role that natural populations of cyanobacteria play in maintaining the long-term fertility of paddy soils for rice cultivation, inoculating rice fields with cyanobacterial mixtures is currently a standard agricultural practice in some Asian countries. The symbiotic association *Anabaena*/*Azolla* (see 'symbioses') is intensively cultivated in the Far East for its use as green manure and as fodder for poultry and swine; written instructions for this practice date to 500 BCE.

There are many cyanobacterial metabolites considered as "high-value products". Carotenoids such as beta-carotene and astaxanthin, as well as the phycobilin phycocyanin are commercialized as food colorants. Chlorophyll *a*, radiolabeled nucleotides, amino acids, and some restriction endonucleases of cyanobacterial origin are sold for research purposes. There are many examples of cyanobacteria bioactive compounds with antibacterial, antifungal, and antiviral properties. Furthermore, the production of biopolymers such polyhydroxyalkanoates (PHAs) by cyanobacteria are used as a biodegradable alternative to petroleum-based plastics, especially in the biomedical industry.

The possibility of using cyanobacteria to produce biofuels is currently being pursued by a variety of academic and industrial ventures worldwide. Cyanobacteria are especially attractive for this purpose since they require only sunlight and water and can incorporate atmospheric or water-dissolved CO₂ into hydrocarbons for biofuels. Biofuel products produced by cyanobacteria include biodiesel, alcohols (e.g., ethanol, butanol), aldehydes, terpenoids (e.g., isoprene), alkanes, free fatty acids, hydrogen, and ethylene. For example, high levels of hydrogen were produced by a wild-type strain of *Cyanothece* sp. ATCC 51142 under aerobic conditions in the presence of glycerol, and *Lyngbya aestuarii* produces naturally copious hydrogen from the fermentation of photosynthate. However, an added benefit of using cyanobacteria to produce these biofuels is that many strains can be genetically manipulated to increase yields. Approaches to optimize the metabolic capability of cyanobacteria to synthesize these products include improving rates of CO₂ fixation, optimizing pathway flux, increasing tolerance to toxic products, and elimination of competing pathways. Modification of the glycolytic pathway of *Synechococcus elongatus* PCC 7942 resulted in increased shuttling of CO₂ to the Calvin-Benson cycle and production of 2,3 butanediol in the presence of light. Furthermore, alkane production was accomplished by heterologous expression of a two-gene operon from *Synechococcus elongatus* PCC 7942 in *E. coli* to produce a mixture of C13 to C17 alkanes and alkenes. Another approach to increasing the efficiency of using cyanobacteria for fuel production is to improve downstream processes, such as biomass extraction. In *Synechocystis* sp. PCC 6803 a strain capable of secreting free fatty acids was engineered to improve the secretion of some fatty acids up to 30% compared amounts secreted by the wild type.

EDITOR-IN-CHIEF

Thomas (Tom) Schmidt is a microbial physiologist and ecologist who studies diverse microbes and microbial communities. Tom received a PhD from The Ohio State University and conducted postdoctoral research at Scripps Institute of Oceanography and Indiana University. He spent much of his career studying the ecology of microbes in soil that are responsible for the exchange of greenhouse gases with the atmosphere. More recently, he joined the University of Michigan and focused his research on the human microbiome. His joint appointment in the Departments of Internal Medicine and Ecology & Evolutionary Biology reflects his expertise in applying ecological and evolutionary principles to understand the functioning of complex microbial communities.

Tom is a fellow of the American Academy for Microbiology and was director of the Marine Biological Laboratory's Microbial Diversity Course in Woods Hole. Through that course and in his laboratory, he has helped numerous scientists incorporate molecular approaches into traditional strategies for studying the microbial world. He currently teaches a university course that merges his research and teaching goals by engaging students in a coordinated study of the effects of diet on the gut microbiome, and he directs a graduate program that combines laboratory sciences and modeling. Tom was a section editor for previous editions of the *Encyclopedia of Microbiology* and was delighted to assume the role as editor-in-chief to help bring the microbial world to an expanding audience.

EDITORIAL BOARD

Bianca Brahamsha is a research microbiologist at Scripps Institution of Oceanography at the University of California, San Diego. She was a biology and history major at Goucher College, earned her PhD in microbiology at Cornell University, and carried out postdoctoral work in molecular genetics as an American Cancer Society fellow at the University of Chicago. Her research interests have centered on bacterial motility, the genetics and physiology of marine cyanobacteria, and on the interactions between cyanobacteria and their eukaryotic predators.

James (Jim) Brown was born in Atlanta, Georgia, and lived in Dade City (Florida), Bloomington (Indiana), Lima (Peru), and Muncie (Indiana) while growing up. From the beginning, he had an intense interest in nature, including anything found in the woods, rivers, beach or ocean that were always nearby.

Jim attended Ball State University beginning in 1976. A single lecture on microbial diversity in a general microbiology class, followed by the announcement of the discovery of the Archaea (George Fox and Carl Woese, 1977), sparked his lasting interest in microbiology. This led to undergraduate research examining *Beggiatoa* in a sulfur spring in French Lick, Indiana. After receiving his BS in biology in 1980, he joined the graduate program in microbiology at Miami University, where he worked on plant tissue culture mRNAs with Prof. Ronald Treick. After obtaining an MS degree in 1982, he moved to the MCD Biology Program at The Ohio State University to work on the molecular biology of methanogenic Archaea in the Department of Microbiology with Prof. John Reeve. While there, Jim worked on polyadenylation of mRNAs, RNA polymerase, and promoters in Archaea, and received his PhD in 1988. Jim then went to Indiana University for 5 years of postdoctoral work in Prof. Norman Pace's lab on the comparative analysis of the structure of a bacterial ribozyme, RNase P.

In January of 1994, Jim started as an assistant professor in the Department of Microbiology and moved to North Carolina State University. Research in Jim's lab focused on the comparative sequence and biochemical analysis of RNA, and in particular RNase P in Archaea. Students in the Brown lab developed a high-resolution model for the structure of this RNA, how it changed over the diversification of the Archaea, the protein subunits associated with the RNA, and how they contribute to the function of the holoenzyme. Jim developed, teaches, and wrote the textbook for a senior-level undergraduate lab course in microbial diversity. Jim is now Professor Emeritus in the Department of Biological Sciences at NC State University.

Jim has a son and two daughters, and is married to Melanie Lee-Brown, professor of biology and director of Research and Creative Endeavors at Guilford College. For fun, Jim enjoys skin and scuba diving, driving (i.e., working on) his 1968 Lotus Super Seven, and restoring vintage racing bicycles. Jim and Melanie have been renovating an abandoned fishing lodge on North Caicos Island (Turks and Caicos Islands, BWI), which will be reopened soon as a bed and breakfast.

Larry Forney is a university distinguished professor and a member of the American Academy of Microbiology with academic appointments in the Department of Biological Sciences and Bioinformatics and Computational Biology at the University of Idaho. Dr. Forney is an evolutionary ecologist who conducts research on the complex array of factors that influence the function, composition, structure, and temporal dynamics of bacterial communities in a wide array of habitats. In recent years he has largely focused on the community ecology of the human vagina across a woman's lifetime with an eye on understanding how changes in community structure and function affect a woman's risk to bacterial vaginosis, sexually transmitted infections, and pre-term birth, and how host factors shape these communities. His research extends to understanding the mutation-selection processes that govern the occurrence and persistence of genetic diversity of bacterial populations in spatially structured environments such as microbial biofilms and porous media. These studies have shown that spatial structure creates condi-

tions in which mutation frequencies are high and selective sweeps are protracted, which leads to extraordinary within species diversity that increases the resilience of populations to environmental changes.

Robert Haselkorn was the F. L. Pritzker distinguished service professor of molecular genetics and cell biology at the University of Chicago, retiring several years ago. He was an undergraduate at Princeton, a graduate student at Harvard, and a postdoctorate in Cambridge, England. He started his teaching career at Chicago in 1961 in biophysics, extending later to microbiology, biochemistry, and chemistry. His research interests have centered on heterocyst differentiation in nitrogen-fixing cyanobacteria, in bacterial genomics, and in the enzyme acetyl-CoA carboxylase in plants, parasites, and people. He is a member of the National Academy of Sciences, a fellow of the American Academy of Arts and Sciences, and a member of the American Philosophical Society. Among other external activities he was a founder and adviser for 20 years to the International Center for Genetic Engineering and Biotechnology, located in Italy and India. For the past 15 years Haselkorn and his wife Margot have been working on selection and supporting a speaker for the Haselkorn Lecture at the University of Chicago,

an award they have endowed. Many of the Haselkorn Lecturers have been Nobel Prize winners or will be soon.

Jennie C. Hunter-Cevera received her PhD from Rutgers University in 1978 (microbial physiology and biochemistry), an MS in microbial ecology in 1972, and a BS in biology from West Virginia University in 1970. She is the founder of Hunter and Associates, a consulting firm focusing on finding integrative solutions to complex problems involving sustainability in the life sciences arena. From July of 2009 to August 2012, she was the executive vice president of Discovery and Analytical Sciences (DAS), Corporate Development and Government Relations. She has 22 years of experience in the pharmaceutical and biotechnology industries (E. R. Squibb and Sons, Cetus Corporation, GeoBiotics, and Universal Foods). She was the co-founder of The Biotic Network and Blue-Sky Laboratory that contracted with biotechnology and pharmaceutical companies on basic and applied natural product research. Dr. Hunter-Cevera was an

employee for 5 years with the Department of Energy as the head of the Lawrence Berkeley National Laboratory's Center for Environmental Biotechnology. She worked in academia for 10 years as the president of the University of Maryland Biotechnology Institute and 2 years as the Interim Provost of Mount St. Mary's University. She also served as project manager for UC Davis's CIFAR (Center for Industrial Food and Agricultural Research). She has published many papers and chapters, and served as senior editor of the *Journal of Industrial Microbiology and Biotechnology* for 10 years. She is a co-section head of microbiology for Faculty of 1000. She holds 15 patents and specializes in areas of screen design for the discovery of natural compounds in the area of human therapeutics, biodefense, sustainable agriculture, bioremediation, and biocatalysis for industrial processes in the food and clothing industries.

While in Maryland, she served as a member of the Executive Committee for Governor Ehrlich's transition team, his Committee on science, technology, engineering, and maths, and was the Technology Representative for Governor Glendenning on the Southern Governor's Association, and she served on the Technology Economic Development Corporation, TEDCO (Board of Directors for 4 years and was Chair for 2 years). Dr. Hunter-Cevera also served on the Advisory Board for the Maryland Industrial Partnerships, the MDBio's Board of Directors, and the MDBio Foundation for 10 years and on the BioIT Coalition for 5 years. She served as an Entremed Board Member for 10 years and served on the Executive Committee for 2 years. She was a board member for Patients with Power, a software company that designs programs for cancer patients to make the best decisions for their treatments. Jennie also served as acting secretary for Maryland's Higher Education Commission in 2015.

She is a member of several professional societies and has served as president of the Society for Industrial Microbiology, the International Marine Biotechnology Association, and the United States Federation of Culture Collections. Dr. Hunter has served on many national committees and commissions and was Chair of the National Research Council's Committee on Large Scale Production of Biofuels from Algae. She also chaired two other NRC Committees: Standing Committee on DOD's Translational Medicine and the DOE's Genome to Life for Biofuels.

She is the recipient of several awards and honors including Maryland's Top 50 Influential People (2007, 2009) and Maryland's Top 100 Women (2003, 2006, 2009), American Society for Microbiology's Porter Award for distinguished research in microbial systematics and taxonomy, elected as a SIM fellow, a member of the ASM Academy of Microbiology, and an AAAS fellow. She is also a WVU Distinguished Alumni Awardee and Nath lecturer and served as an entrepreneurial coach for the UNC Executive MBA program. She was awarded an Honorary Doctorate from West Virginia University, May 2013, and the Rutgers Cook College Dennis M. Fenton Distinguished Graduate Alumni Award in 2014.

She currently serves on the International Advisory Council for Brazil's Fundação Dom Cabral which is a world-class Brazilian business school that develops strategic thinking skills of executives, entrepreneurs, and public-sector managers. In addition, Jennie served 6 years on the Edison Awards Steering Committee and currently serves on the Edison Awards Advisory Board.

Stanley Maloy is a professor of microbiology and associate vice president for research and innovation at San Diego State University. Stanley's research has focused on bacterial and phage genetics and physiology, evolution of infectious diseases, and development of antimicrobials and vaccines. In addition, he has consulted with large and small companies in multiple sectors, played a role in starting several Biotech companies, and served leadership roles in multiple start-up companies.

Dr. McCormick earned her PhD in microbiology in the topic area of intestinal ecology, and completed postdoctoral training at Harvard Medical School. She remained on the faculty of Harvard Medical School where she was an associate professor of pediatric gastroenterology, and director of research for the Mucosal Immunology and Biology Research Center at Massachusetts General Hospital. In 2008, she joined the University of Massachusetts Medical School where she is professor and vice chair of the Department of Microbiology and Physiological Systems. Dr. McCormick is also the founding executive director of the University of Massachusetts Center for Microbiome Research, which she established in 2014. Dr. McCormick is one of the original pioneers in the field now known as cellular microbiology. Her work provided the first evidence that epithelial cells in response to pathogen contact orchestrate a pro-inflammatory program, which recruits inflammatory cells. Dr. McCormick has since identified new, previously

unidentified and unexpected virulence mechanisms that are key to the inflammatory response, leading to both novel biological principles of host-microbe interactions and therapeutic intervention strategies for the treatment inflammatory bowel disease, and cancer. Her work continues to identify novel ways in which microbes interact with the intestinal epithelium, publishing over 100 original research papers and opinion pieces in this area. Dr. McCormick is an elected fellow of the American Academy of Microbiology, is on the Board of Editors for *Gastroenterology*, and *Gut Microbes*, and serves as a member of four Editorial Review Boards.

Dr. Mobley received his BS degree in biology from Emory University in 1975 and his PhD degree in microbiology and immunology from University of Louisville in 1981. He conducted postdoctoral training in biological chemistry and then bacterial genetics in the Center for Vaccine Development at the University of Maryland School of Medicine. He served on the faculty at the University of Maryland School of Medicine from 1984 until 2004 in the Division of Infectious Diseases (1984–97) and then the Department of Microbiology and Immunology (1997–2004) where he led the graduate program. During that time, he held a joint appointment in the Department of Biochemistry and Molecular Biology and trained graduate students in that program. In 2004, Mobley moved to the University of Michigan to chair the Department of Microbiology and Immunology and was installed as the inaugural Frederick G. Novy Collegiate Professor of Microbiology and Immunology.

Dr. Mobley's research interests focus on the molecular mechanisms of bacterial pathogenesis and on the fundamental basic research that will lay the groundwork for future therapeutics and vaccines. His lab studies virulence mechanisms of uropathogenic *Escherichia coli* and *Proteus mirabilis* that cause uncomplicated and complicated urinary tract infections, respectively, and, in the recent past, *Helicobacter pylori* that causes gastritis and peptic ulcer disease. For *E. coli* and *Proteus mirabilis*, his lab is focused on identifying surface-exposed proteins that are both synthesized by the bacteria during a urinary tract infection and conserved among uropathogenic *E. coli* and *Proteus* strains. Using these conserved antigens, his lab is determining the efficacy of candidate proteins as components of a multivalent subunit vaccine to protect against urinary tract infection.

Dr. Mobley is a fellow of the American Academy of Microbiology and a fellow of the American Association for the Advancement of Science and a member and past president of the Association of Medical School Microbiology & Immunology Chairs. He was the recipient of the inaugural University of Michigan Postdoctoral Association Excellence in Mentorship Award in 2012. He is a member of the editorial review boards of *Infection and Immunity* and *Microbiology Spectrum* and has served as a study section member for the National Institutes of Health. Dr. Mobley was awarded and named a distinguished university professor in 2015. This is the University's most prestigious professorship established to recognize senior faculty with exceptional scholarly achievements, national and international reputations for academic excellence, and superior records of teaching, mentoring, and service.

Dr. Mobley has published 255 peer-reviewed articles which have been cited in the literature over 18,000 times as of June 2019, as well as 49 book chapters and 5 books. He has trained 29 PhD students and 38 postdoctoral fellows, and has delivered 232 invited lectures in 21 countries.

Carlos Pedrós-Alió graduated in biology at the Autonomous University of Barcelona and got his PhD in bacteriology at the University of Wisconsin–Madison. After a postdoctoral stay at the Autonomous University he became an assistant professor of microbiology. He moved to the Marine Sciences Institute (CSIC, Barcelona) in 1989 where he was a research professor since 2000. In 2016 he moved to the National Center for Biotechnology (CSIC, Madrid). Dr. Pedrós-Alió's interest is to understand the ecology of aquatic microorganisms. Around 2005 he started to use genomics as a tool to generate hypotheses that could later be tested experimentally. He also likes to study extreme environments such as hypersaline systems, thermal springs, or polar waters. Another interest is in finding the mechanisms maintaining a large number of rare bacteria in aquatic ecosystems. He is also interested in outreach, relationships between art and science, biology of spirituality, fiction writing, and birding.

PREFACE

As with previous editions of the *Encyclopedia of Microbiology*, the 4th edition takes on the challenge of providing a contemporary overview of microbes—the most abundant and diverse forms of life on Earth. These single-celled organisms were the first life forms to inhabit Earth and they transformed the planet and its atmosphere. They continue to maintain Earth's atmosphere, drive essential processes in terrestrial and aquatic ecosystems, and form intimate relationships with all plants and animals. Microbes can reproduce by doubling every 20 minutes or can remain dormant for many thousands of years. They colonize every known habitat on Earth, accounting for approximately half of the living biomass on our planet. Microbes also cause the most devastating diseases known to humans and are winning the antibiotic war we wage against them. Yet, we cannot live without microbes as symbionts of humans and drivers of Earth's biosphere.

Despite the central roles of microbes, we are only just becoming aware of our limited knowledge of interactions among microbes, other organisms, and the environment. Molecular techniques continue to lead a revolution in our understanding of microbial diversity and function, with the new “big data” sciences of genomics, transcriptomics, proteomics, and metabolomics now being applied to communities of microbes. These techniques provide the ability to identify and study complex communities of microbes in diverse environments including the human gut, forest soil, water-treatment biofilters, and the open ocean.

Given the remarkable physiological and phylogenetic diversity of microbes, their capacity for rapid evolution, and the pivotal role of host-associated and environmental microbiomes, it is difficult, if not impossible, to identify contemporary questions in biology that are not influenced by microbes. It is also increasingly difficult to assemble an encyclopedia that provides comprehensive coverage of the vast universe of microbes. Despite these challenges, we have engaged the expertise of scientists around the globe to provide an exceptional overview of and perspective on the microbial world. This edition of the *Encyclopedia of Microbiology* will help readers develop a framework for understanding microbes and will provide references directing readers to the primary literature that is needed for a more thorough appreciation of specific topics.

We have included a number of articles which provide a historical perspective of microbiology that is focused on disease—one of humanity's earliest acknowledgment of microbes. These help frame more contemporary issues in microbiology that have moved far beyond the relatively small collection of microbes that cause disease. Rather than simply alphabetize topics as in traditional encyclopedias, articles in the 4th edition are also listed under the following themes in a Subject Classification: Historical, Microbial Diversity, Physiology and Genomics, Ecology and Evolution, Pathogenesis and Immunology, and Technological Advances and Applied Microbiology. We hope this helps readers navigate the work more effectively.

On behalf of an insightful and collegial editorial team, I hope that you emerge from your forays into the *Encyclopedia of Microbiology* with some of the awe that we share for the elegance and power of the microbial world.

Thomas M. Schmidt
Editor-in-Chief

INTRODUCTION: MICROBIAL DIVERSITY

It is what we think we know already that often prevents us from learning.

—Claude Bernard

One of the difficult lessons for any professional scientist is that, as much as we know, as good as our tools and questions are, our knowledge is crude and far smaller than we imagined when we were students. Particularly troublesome is that most fundamental aspects of various scientific fields are simply not very well understood. The physicist wonders what, exactly, “time” is, how space is structured, and why the Planck Constant is $6.62607004 \times 10^{-34} \text{ m}^2 \text{ kg/s}$ instead of any other number you might care to choose. Chemists argue about the nature of a covalent bond, or whether or not transition states exist in reality. Biologists are at a loss to describe how life originated, or even what exactly life (in a general sense) actually is. In the most important book of modern times, “On the Origin of Species,” Charles Darwin clearly (but not concisely) deconstructs the idea of the biological “species,” and despite what many of us learned in school, our view of the “species” even for multicellular sexually reproducing creatures remains murky. The modern reader of “On the Origin of Species” might be forgiven for concluding that the reason for this is that it is the actual *biology* of species, and by extension “life,” our origin, etc., rather than our concepts of them, that are fundamentally disordered.

The subject of this section of the Encyclopedia is Microbial Diversity. What does this mean? What is “microbial diversity?”

Let us start with “microbial.” Literally speaking, the term “microbial” means small living things, usually understood to mean life too small to see with the unaided eye. The scientific field of microbiology, however, mostly emerged from our need to solve crucial health dangers created by a tiny fraction of microbes. As a result, “microbiology,” and so “microbes,” refer to Bacteria (and in modern times the Archaea), fungi, a scattering of problematic single-celled or small multicellular eukaryotes, and the physiological systems of the human body that manages our interactions with these creatures. This sells the microbial world very short. For 85% of the history of our planet, life was *entirely* microbial, and it remains *predominantly* microbial. In the words of Stephen J. Gould, “*We live now in the ‘Age of Bacteria.’ Our planet has always been in the ‘Age of Bacteria,’ ever since the first fossils—bacteria, of course—were entombed in rocks more than 3 billion years ago. On any possible, reasonable or fair criterion, bacteria are—and always have been—the dominant forms of life on Earth.*” Another view of this comes from the phylogenetic perspective. If you scrutinize any objective/quantitative “Tree of Life,” based on molecular sequence analysis or any other criterion of choice, you will quickly discover that nonmicrobial life is limited to the tips of a small number of otherwise un-noteworthy branches. Only from our self-centered anthropocentric viewpoint is microbiology distinguishable from biology as a whole.

And what of “diversity?” Living things and their morphology, structure, physiology, ecology, internal mechanisms, behavior, interactions, etc., are far more diverse than most of us have been led to believe. For example, if you think you know how mitosis works, look it up in *Giardia* and be amazed. The notion of what constitutes a “gene” in the kinetoplast of *Trypanosoma* requires you to throw almost everything you think you know about molecular genetics away. Then have a look through the genome of the archaeon *Nanoarchaeum*. These are just the tips of icebergs; these and many more can be found within the chapters that follow. And yet . . . all of this diversity rests over an almost entirely uniform biochemistry that speaks to the shared ancestry of all living things on Earth. How, then, do we assess the “diversity” of living things? Historically, this meant comparing the morphology of different living things; this was the origin of Linnaean taxonomy and, to be fair, is very useful for organisms on the human size scale. More recently molecular phylogenetics has allowed us to more clearly understand how creatures are related, and draw an objective and quantitative graph of these

relationships; the molecular “Tree of Life” is a more useful roadmap of biological diversity. But it is clear that an even more sophisticated view of biological diversity is required, for example to describe how horizontal gene transfer impacts “diversity,” and many of these questions emerge from microbiology. Perhaps the most important fundamental question in microbiology today is “What is a microbial species?” In other words, how do we conceive of a “species” in organisms that do not reproduce sexually? This is not a trivial or parochial question; remember that the concept of biological evolution, and so the foundation of the science of biology, emerged directly from exploration of what a “species” is and how it originates, in plants and animals. But this was over 150 years ago. Broadening our view of microbial diversity, how it is structured and its history and origins, is the key to new and deeper biological insight.

And so, as is usual in science, attempt to answer a simple question that raises many more questions and provides few answers. What *is* microbial diversity? I dunno, but let us have a look. . . .

James Brown

INTRODUCTION: PHYSIOLOGY AND GENOMICS

The first two editions of EOM were edited entirely by Dr. Joshua Lederberg. The third edition was also planned largely by Dr. Lederberg, but he died during that phase, in 2008, and was replaced by Dr. Moselio Schaechter, promoted from the ranks of associate editors. Dr. Thomas Schmidt was also an associate editor for that edition and moved up to editor-in-chief for the fourth edition.

The time that has passed from the first to the fourth edition has seen remarkable advances in understanding the variety of microbes. Complete genome sequences were determined for 18 microbes by October 1998 and published in the second edition in 2000. By 2019, a single company had determined the complete annotated genome sequences of several thousands of microbes. Comparative genomics, including the ancillary “omics,” as well as the application of systems biology to reconstruct metabolic networks, have provided new insights into many aspects of microbial physiology and genetics. The advent of cryo EM and of single particle cryo EM has revolutionized how we understand the structure of cells and macromolecules. For this fourth edition, we were guided by the splendid organization of the third and additional areas in which considerable advances have been made. The fourth edition now includes articles describing additional features of microbiology: cryo-electron microscopy, CRISPR/*cas*, and metabolic systems biology, as examples of completely new methods to study microbes, circadian rhythms as an important aspect of the physiology of at least one group of microbes, and new developments in our understanding of the many ways in which bacteria and archaea move. We have also made use of updates of chapters that were included in the third edition.

Bianca Brahamsha
Robert Haselkorn

INTRODUCTION: ECOLOGY AND EVOLUTION

Evolution

Seven articles deal with different aspects of evolution. Two articles analyze the remains of the past evolution of microbes in the fossil record. Three other look at theories, mechanisms, and experimental procedures. Two more examine specific aspects of the evolution of viruses and of a ciliate. Finally, one article bridges ecology and evolution looking at the emerging field of evolutionary ecology of microbes.

Ecology

The ecology section contains a few general articles about what microbial ecology is about, and the particularities of the ecology of viruses and rare microorganisms.

The remaining articles can be placed in two complementary approaches: habitat oriented or process oriented. In the first approach there is a lot of attention devoted to extreme environments. These environments are usually exclusively microbial and show the capacity of microbes to deal with really difficult conditions. Besides, the relative simplicity of such ecosystems allows somewhat easier manipulations than in “normal” ecosystems. Several of the latter are also examined in articles ranging from the deep ocean to plastics. Special attention is given to animal and plant habitats and how microbes interact with their hosts.

The process-oriented approach shows, on the one hand, adaptive traits of microorganisms such as the ability to live in diluted environments or to use chemotaxis to find the optimal conditions. One promising and novel avenue to study adaptations is the analysis of the genomes of uncultured microorganisms. On the other hand, several articles review processes relevant at the ecosystem level, from feeding strategies such as myxotrophy to element cycles such as methane formation and oxidation and, finally, to the use of models in microbial ecology.

We hope this collection of articles provides an overview of the exciting times that microbial ecology is going through, with many new discoveries appearing every few years, and a fascinating and invisible world to be explored.

Carlos Pedrós-Alió
Larry Forney

INTRODUCTION: PATHOGENESIS AND IMMUNOLOGY

This section of the encyclopedia focuses on the relatively narrow slice of all microbes that infect living hosts and how the hosts combat these microbes using innate and adaptive immunity. In addition, we examine how antimicrobial agents including unique metabolites and even bacteriophages have been enlisted to combat these infections. This section takes a broad look at infectious agents ranging from prions, viroids, and satellites to the more traditional etiologic agents like bacteria, viruses, fungi, and selected parasites. Also addressed are epidemiologic and diagnostic techniques used to identify and track the spread of infectious microbes including the most advanced diagnostic methods used by the clinical microbiology laboratory. A closer look at pathogenic mechanisms includes groups of virulence factors such as adhesins, iron acquisition, exotoxins of bacteria and fungi, and bacterial endotoxin (lipopolysaccharide). Strategies adopted by bacteria and fungi to colonize implanted foreign bodies such as catheters are also discussed. Plus, infections of the gastrointestinal tract, lung, oral cavity, and the skin are examined. In addition to pathogenic microbes, some articles examine the protective effect of the microbiome and commensal organisms. With respect to immunity this section also focuses on the interplay of the host immune system with pathogenic microbes covering evasion immune strategies in humoral and cellular immunity as well as innate immunology and the complement immune system.

Beth McCormick
Harry Mobley

INTRODUCTION: TECHNOLOGICAL ADVANCES AND APPLIED MICROBIOLOGY

This section focuses on the development and refinement of the tools commonly used for both basic and applied microbiology. The articles in this section are written by authors who personally have worked on developing and fine-tuning technology for research in microbiology. Many of the products and processes described have multiple uses in a variety of disciplines such as health, the environment, food and agriculture, and industrial biocatalysis. The advances made in sequencing, protein analysis, and bioinformatics have given microbiologists new insights into old problems. These advances have also enabled the rapid identification of microorganisms in studies of biowarfare, infectious disease, and pollution of our water sources. At the same time the integration of mathematics and physics with biology and chemistry has provided instrumentation that enables a greater depth of analysis than ever before. Never in the history of microbiology have so many technological advances been developed and commercialized for use by scientists. Microbiologists today are equipped with improved “tools” within the toolbox to push the boundaries of not only elucidating the relationship of microbes to humans, plants and animals but also moving basic research much faster from the bench to development of new products and processes that benefit society and the planet. The renaissance of applied microbiology powered by technological advances has been both exciting and promising in all fields of study.

Defining Statement

Diagnostic microbiology determines if microorganisms present in specimens collected from human beings, animals, and environment, are pathogens. Additionally, it defines infectious processes and aids in the management and treatment of patients based on the detection, quantification, and characterization of specific pathogens. This module provides an overview of the fundamental principles and techniques of diagnostic microbiology.

[☆]*Change History:* June 2019, M. Cintrón, J. R. Hauser, C. Otto, D. H. Persing, and Y.-W. Tang updated the text, references and figures.

This article is an update of C. Otto, D.H. Persing, Y.-W. Tang, *Diagnostic Microbiology, Reference Module in Biomedical Sciences*, Elsevier, 2014.

Development of Diagnostic Microbiology

Diagnostic microbiology dates back to over three centuries when van Leeuwenhoek first observed bacteria and protozoa with his primitive microscope. However, it was not until the late 1800s that the work of Pasteur, Koch, and others ushered in the modern era of germ theory as well as the use of isolation techniques on artificial growth media. Since then, the capabilities of modern diagnostic microbiology have expanded and rapidly improved due to technological revolutions in microbiology, immunology, and molecular biology. A microorganism in a sample can be detected and identified by: (1) cultivation using artificial media or living hosts, (2) direct microscopic examination, (3) measurement of microorganism-specific immune responses, and (4) detection of microorganism-specific macromolecules, especially nucleic acids and antigen detection. The contrast of these techniques is summarized in Table 1, the following sections will discuss them separately.

During the last 30 years, diagnostic microbiology has significantly evolved. Until the early 1970s, definitive laboratory diagnoses of infectious diseases had been largely accomplished through the use of cumbersome, costly, time-consuming, and often subjective techniques. However, in the 1980s and 1990s, advances in molecular techniques were routinely incorporated within the laboratory. The development of radioimmunoassay and immunofluorescence, enzyme immunoassay (EIA) and immunoblotting, became routine diagnostic microbiology applications. These techniques, especially EIA, have supplanted many labor-intensive and relatively insensitive and nonspecific procedures such as complement fixation and hemagglutination inhibition assays for viral serology. Commercially available direct immunoassay kits make detection of certain important groups of viruses, such as respiratory syncytial virus and rotavirus, practical and economical. Application of monoclonal antibodies and antigen-recognizing probes, such as peptides, has significantly increased the sensitivity and specificity of antigen detection.

Direct microorganism identification based on antigen or nucleic acid detection through immunologic and molecular techniques has significantly shortened the test turnaround time. Oligonucleotide probes were used for culture confirmation and differentiation of slow-growing microorganisms, such as mycobacteria. Specialized nucleic acid hybridization probes, such as peptide nucleic acid (PNA) probes, are used for in-situ identification of organisms to the species level under a fluorescent microscope. Automated or semiautomated computerized commercial systems are now available for microorganism identification and antimicrobial susceptibility determination. Bacteremia and fungemia are now often detected by automated, instrument-assisted blood culture systems, which have significantly improved the sensitivity and specificity for detecting most such pathogens and, by virtue of automation, have eliminated much of the hands-on time for detection of positive cultures.

One of the greatest advances in the field of diagnostic microbiology has been in nucleic acid detection. The polymerase chain reaction (PCR) and other amplification techniques have simplified and accelerated the *in vitro* process of nucleic acid amplification. Rapid techniques of nucleic acid amplification and characterization, along with the increased use of automation and user-friendly software, have significantly broadened microbiologists' diagnostic arsenal. New real-time PCR, multiplex PCR, and microarray techniques provide relevant and accurate microbial quantification and typing, which play important roles in the selection and monitoring of antimicrobial therapy.

Advances in omics-based approaches (genomics, proteomics, and metabolomics) have led to their use in diagnostic microbiology and epidemiology. The development of robust next-generation sequencing platforms has dramatically increased sequencing capacity and reduced cost per base. These changes have made sequencing more accessible for the diagnostic laboratory such that sequencing is becoming a routine diagnostic tool in many laboratories. One of the most revolutionary technologies within the diagnostic laboratory has been the implementation of mass spectrometry (MS)-based microbial identification and characterization. Besides providing accurate and rapid identification of microorganisms, it has also significantly impacted laboratory costs (Patel et al., 2017; Perez et al., 2013). Transcriptomic and metabolomic profiles have also been shown to have clinical utility. Changes in transcriptomic and metabolite profiles can be used to diagnose and monitor severe microbial infections and differentiate between bacterial and viral infections (Barral-Arca et al., 2018; Herberg et al., 2016; Warsinske et al., 2018).

Table 1 Methods used for microorganism diagnosis.

Test	Ease of performance	Turnaround time	Result interpretation	Advantages	Disadvantages
Direct examination	Can be performed in routine clinical laboratory and in nurse station	1–3 h	Direct if correlated with symptoms	Rapid	Poor sensitivity and specificity; special skills are needed for interpretation
Culture	Can be performed in sophisticated clinical laboratory and in research laboratory	2–14 days	Definite; gold standard for most infection diagnosis	For phenotypic drug susceptibility testing	Time-consuming; poor sensitivity; limited microorganisms are culturable
Serology	Can be performed in larger and sophisticated clinical laboratory	4–6 h	Indirect	Automation	Results are generally retrospective; immunosuppressed host may be unable to mount a response
Molecular diagnostics	Can be performed in sophisticated clinical laboratory and in research laboratory	0.5–8 h	Direct without knowing microbial viability	High sensitivity and specificity	Quantification results awaits standardization; results might not be used as a test of cure

In summary, the implementation of these technologies within the diagnostic laboratory has had a positive impact in patient care. The old diagnostic microbiology model could only service inpatients because the methods used were labor intensive and time consuming. More so, these test results took days to months to be available. Because of the significant reduction in turnaround time, the modern diagnostic microbiology laboratory has gradually begun servicing an increasing number of emergency room patients and outpatient populations.

Direct Identification of Microorganisms

Microscopic Examination

Many test specimens may be examined in their native state under a microscope. A wet mount can be prepared by applying specimens directly onto the surface of a slide, which is often used to detect motile trophozoites of parasites such as *Giardia lamblia* in stools and *Trichomonas vaginalis* in vaginal discharges. Certain bacteria are so thin that they cannot be resolved in direct preparations. Their characteristic motility, however, is an important feature of presumptive identification. Darkfield microscope examination, a method of allowing light to be reflected or refracted off the surface of the object, is used to identify these bacteria; spirochetes, such as *Borrelia burgdorferi*, the microorganism causing Lyme disease, are primarily visualized with this method. This method is also used for the demonstration of motile treponemes in exudates collected from a primary chancre of syphilis.

Direct examination also allows the identification of certain characteristics that represent specific infections. The presence of cytoplasmic morulae in peripheral blood leukocytes is a timely way of confirming *Ehrlichia* infection. Detection of viral inclusions in smears or tissues has been the traditional means of directly demonstrating virus infections. Although not used routinely within the diagnostic laboratory, electron microscopy (EM) has been used to directly detect viral causes of gastroenteritis such as rotaviruses (Brandt et al., 1981).

The most common method of direct examination involves staining either the specimen itself or cultures. Microorganisms may be visualized and assigned to morphologic and functional groups using special stains. Gram stain is the most popular stain used within the diagnostic laboratory. It allows the staining of bacteria and yeast present in test samples. It is most commonly used to classify bacteria based on their forms, sizes, cellular morphologies, and color reactions. Nevertheless, there are other organisms for which Gram stain is not ideal. For example, mycoplasma lack a cell wall, therefore they will not be stained by Gram stain and their presence is visualized using acridine orange. Whereas for bacteria that possess unique cell wall components (e.g., mycobacteria), acid-fast stain is preferred. A modified acid-fast stain is useful for detecting certain parasites present in stool samples (e.g., *Cyclospora*). For systemic protozoa (e.g., malaria), Giemsa stain is the stain of choice. In the case of fungi, Calcofluor white binds to fungal cell walls in the presence of 10% potassium hydroxide, and fungal elements can be observed under a microscope. This allows sensitive direct fungus detection, including *Pneumocystis carinii*, a common opportunistic infection in AIDS and other immunocompromised hosts. Table 2 summarizes common staining methods used in diagnostic microbiology.

Table 2 Stains commonly used for detection of microorganisms.

Stain method	Organisms detected	Advantages	Disadvantages
Gram stain	Bacteria, yeast	Rapid; direct differentiation; assess specimen for culture	Cell wall-deficient bacteria stain unpredictably; pink background often masks Gram-negative organisms
Acridine orange stain	Bacteria, mycoplasma, plasmodia, Babesia	Good for organisms with damaged cell walls; background levels are low for structures that lack nucleic acid	Specific light source is needed; cannot differentiate bacterial Gram status reaction
Acid-fast stain (Kinyoun or Ziehl-Neelsen)	Mycobacteria	Direct diagnosis of infection in untreated host	Cannot speciate mycobacteria; high background in tissue slide
Auramine-rhodamine stain	Mycobacteria	Lower power can be used for examining the slide	Fluorescence microscope is needed; artifact staining in tissue slide
Modified acid-fast stain	Nocardia, Cryptosporidia, Cystoisospora, Cyclospora	Rapid and specific diagnosis	Tissue homogenates often mask presence of the organism
Calcofluor white stain with potassium hydroxide	Pneumocystis, fungi	Rapid stain for fungi detection	Fluorescence microscope with specific filter is needed; species differentiation requires skills
India ink stain	<i>Cryptococcus neoformans</i>	Diagnosis of meningitis when positive in spinal fluid	Low sensitivity; a messy technique with false positives from lymphocytes in hypotonic solution
Giemsa stain	Plasmodia, trypanosomes, Leishmania, Toxoplasma, Histoplasma, Pneumocystis	Detection of multiple organisms; shows the relationship between organisms and host cells	Not specific for viral inclusions; cannot determine bacterial Gram status

Microbial Antigen Testing

Immunological approaches to the detection of microorganisms' protein antigens remain important tools for the diagnosis and management of infectious diseases. Great technical advances have been made since the introduction of the early precipitation and agglutination assays. For immunologic detection of microbial antigens, latex particle agglutination, immunofluorescence assay, and EIA are the techniques most frequently used. Antibodies to a specific antigen are bound to latex particles to produce agglutination. This technique has been extremely useful in the detection of *Cryptococcus neoformans* in bodily fluid specimens, such as plasma and cerebrospinal fluid. Direct immunofluorescence assay has been included in the shell vial technique for rapid virus culture detection (see below) and the detection of *Legionella pneumophila* in sputum.

There are several approaches to enzyme-linked antigen detection assays; the one most frequently designed for the detection of microbial antigens uses an antigen-specific antibody that is fixed to a solid-phase well in a plastic tray. Antigen present in the specimen binds to the antibody. The test is then completed by adding a second antigen-specific antibody bound to an enzyme that can react with a substrate to produce a colored product. Lateral flow chromatographic immunoassays (CIA) have been introduced to rapidly detect several respiratory virus-specific antigens and cryptococcal antigen. CIAs consist of a test strip which contain immobilized antigen specific antibodies conjugated to a chromogenic label. If the antigen is present in the patient's sample, it binds to the antibodies and the antigen-antibody complex continues to migrate laterally up the test strip via capillary action until it reaches the test line. The test strip contains a secondary antibody that captures the antigen-antibody complex. The accumulation of antibody-antigen complexes at the test line produces a band indicating a positive reaction. In comparison to regular EIA procedures, these lateral flow CIA-based procedures require very little hands-on time and often are capable of a fast test turnaround time. Some of them require a hands-on time of only 1–2 min, have only one incubation period, and are very easy to interpret and can be semiquantitative (Theel et al., 2015).

The use of microorganism-specific monoclonal and recombinant antibodies has improved reagent availability and reproducibility and enhanced test specificity. Examples include rapid viral antigen detection kits, which have been used widely in the clinical virology laboratory for the rapid detection of influenza virus, respiratory syncytial virus, and rotavirus in clinical specimens, though these techniques are steadily being replaced by PCR-based methods (see below). To overcome the time-consuming and costly procedure for natural antibody production, phage display has been used to discover antigenic peptides, which are either chemically synthesized or produced in *Escherichia coli*, and used to produce antibodies that can be probes for microbial antigen detection. They have been used for the detection of antigens of *E. coli* O157:H7, *Borrelia*, Epstein-Barr virus, and panels of biological threat agents.

Genetic Probe Hybridization

The ribosomal RNA (rRNA) possesses distinct features that make it a good universal marker for bacterial identification. Molecular biology has exploited this characteristic to design methods to target these "signature" sequences. DNA or RNA probes complimentary to these unique nucleotide sequences within the rRNA of a microorganism serve as a way to detect the presence of the organism itself. These probes are linked with reporter molecules that allow visualization of hybridization reactions without the need to amplify the target sequence. In general, nonamplified-probe based techniques are used in diagnostic microbiology primarily for culture confirmation of organisms after a brief period of *in vitro* cultivation. Because they provide a fast and reliable result, probe assays are routinely used within the laboratory. They are useful in identifying organisms that can take a long time to grow in culture (e.g., *Mycobacterium tuberculosis*). Gen-Probe, Inc. (San Diego, CA, USA) and Becton, Dickinson and Company (Sparks, MD, USA) make several culture identification nucleic acid probes that have been approved by the FDA. These can be used for mycobacterial, fungal, and bacterial identification.

Other companies have developed other assays that are currently not FDA-approved yet offer the ability to quickly identify microorganisms with suspected pathogenicity present in clinical samples. As an example, AdvanDx Inc. (Woburn, MA, USA) offers a panel of PNA fluorescence in situ hybridization (FISH) tests including QuickFISH that allow the identification of common bloodstream infection pathogens directly from positive blood cultures in approximately 30 min (<http://www.opgen.com/pathogenid/pna-fish-products/>). Although these commercial products are more expensive than conventional approaches, the decrease in time-to-identification has the potential to improve patient outcomes and reduce overall health-care costs (Seo et al., 2018).

Microorganism Culture and Identification

Isolation and cultivation of a microorganism, either in an artificial medium or in a living host, is definitive evidence for the presence of a microbe. In many cases, culture techniques remain the "gold standards" for diagnostic microbiology even though lengthy incubation periods preclude the use of the test results as useful diagnostic procedures. Culture is usually the most specific method for establishing the presence of a particular pathogen in a specimen. In addition, a pure culture of either a virus, fungus or a bacterium is essential for performing *in vitro* phenotypic antimicrobial susceptibility tests.

Culture Using Artificial Media

Bacteria, mycobacteria, mycoplasma, and fungi are cultured either in liquid or solid artificial media. Liquid media provide greater sensitivity for the isolation of small numbers of microorganisms since larger volumes of a specimen can be inoculated into broth than onto agar plates. However, liquid media cannot be used for diagnosis of mixed infections and organism quantification cannot be performed unless real-time growth indicators are measured. On the other hand, though somewhat less sensitive than liquid

media, agar media provide the ability to isolate colonies that can be identified, sometimes based on their colony morphologies, and quantified by calculating the number of colony-forming units. The quantification of microorganisms is important when determining if the presence of an organism represents colonization or not.

Some organisms require specific conditions to grow. For example, anaerobic pathogen recovery is achieved by incubating media in an anaerobic environment. An anaerobic container or chamber can be used. Additionally, culture media can be made selective by incorporating compounds such as antimicrobial agents that inhibit endogenous flora, while permitting the growth of specific microorganisms resistant to these inhibitors. This is extremely important in the isolation and identification of pathogenic microorganisms in sputum and stool specimens. For instance, several selective and differential media such as Hektoen enteric, xylose-lysine desoxycholate, and salmonella–shigella agars are available for the isolation and differentiation of enteric pathogens from stool samples. Bile esculin agar plus vancomycin has been widely used as a selective and differential medium for screening vancomycin-resistant enterococci. In some instances, a growth indicator medium can be developed by incorporating one or more carbohydrates in the medium along with a suitable pH indicator. These differential media can be used to isolate and screen for certain microorganisms present in different clinical samples. As an example, many different chromogenic media have been developed to differentiate between bacterial genus and species and between yeast species (Fig. 1). In addition, chromogenic media have been developed to screen for antibiotic-resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and carbapenem-resistant *Enterobacteriaceae* (CRE) (Perry, 2017). Isolation of microorganisms from blood specimens is a major task of clinical microbiology laboratories.

Fig. 1 Chromogenic medium used to (A) Screen for MRSA, mauve colonies (CHROMagar MRSA from Becton, Dickinson and Company) (<https://www.bd.com/resource.aspx?IDX=32508>). (B) CHROMagarTM StrepB plate to differentiate group B streptococci from other streptococci (http://www.chromagar.com/clinical-microbiology-chromagar-strepb-focus-on-streptococcus-agalactiae-30.html#.U-plm_PD9Qs), (C) CHROMagar ESBL is used to select for and differentiate between Gram negative organisms producing extended-spectrum beta lactamase (http://www.chromagar.com/clinical-microbiology-chromagar-esbl-focus-on-esbl-resistance-31.html#.U-pl7_PD9Qs), and (D) Brilliance Candida Agar (Oxoid) differentiates between *Candida albicans* and *Candida tropicalis* from other species of *Candida* within 48 h (http://www.oxoid.com/pdf/24085_oxoid_brilliance_candida.pdf).

Culture Using Living Cells

In the 1960s, it was shown that *Chlamydia trachomatis* could be recovered in eukaryotic cell culture using McCoy cells (Gordon and Quan, 1965; McNabb et al., 2004). Besides *Chlamydiae*, many viruses can be recovered and identified using eukaryotic cell culture. The virologic component of diagnostic microbiology has become increasingly more common with the advent of effective antiviral treatments as well as the need to identify and treat viral infections in the human immunodeficiency virus (HIV)-infected and other immunocompromised hosts. Viral isolation is very sensitive and in theory a positive result can be obtained with a single infectious virion. However, not all viruses can be recovered *in vitro*. Several culture systems have been used for virus isolation, and their characteristics are listed in Table 3. After inoculation, a virus can initially be identified and differentiated by (1) the pattern of the cytopathic effect (CPE), (2) the specific cells in which CPE is induced, and (3) the rapidity of the appearance of CPE. For example, the majority of enteroviruses cause CPE in rhesus monkey kidney cells within 48–72 h (Klespies et al., 1996; Lipson et al., 2001). However, poliovirus-induced CPE appears within 1 day after inoculation, whereas it takes 4 days for echovirus to induce the same amount of CPE. Typically, specimens are inoculated into different cell cultures to provide a susceptible host for each virus that may be present. Some of the most common cell culture cell lines are shown in Table 3.

CPE can be visualized under a light microscope without the need of a stain. Because CPE can be a result of cellular deterioration, direct fluorescent antibody (DFA) tests have been developed to confirm the presence of the virus. Some organisms may take a long time to grow in cell culture or to cause CPE, therefore shell vial isolation has been widely used within the diagnostic laboratory. This technique combines cell culture and antigen detection. It can be used for the detection of several viruses as well as *Chlamydiae*. One of the advantages of this method is that it is a relatively rapid at identifying agents whose identifications may ordinarily take as long as 3 weeks in a traditional tube culture. Vials with coverslips are typically seeded with a monolayer of cells in growth medium. When the cells are nearly confluent, the growth medium is aspirated and replaced by an aliquot of the clinical sample. The vials are centrifuged and then growth medium is added. The vials are incubated for specific times and temperatures (depending on the agent being sought), and the cells on the coverslip are then incubated with fluorescein-conjugated virus-specific antibody directly in the shell vial. The stained coverslip is removed and placed on a slide for examination under the fluorescence microscope. This technique is advantageous specially for the detection of cytomegalovirus (CMV) infections, since CMV-induced CPE is relatively slow to develop. Quidel (San Diego, CA, USA) offers multiple DFA kits that allow the detection of respiratory viruses, enteroviruses, herpes viruses as well as *Chlamydiae* (<http://www.quidel.com/cultures-fluorescent-tests>). They also offer a genetically manipulated cell line that accumulates an enzyme when infected by HSV-1 or HSV-2. This system is known as the enzyme-linked virus inducible system (ELVIS®). This method allows rapid (<1 day) detection of HSV without the need to detect CPE. Additionally, transgenic and cocultured cell lines have been used to enhance the sensitivity of recovery of enteroviruses and eliminate the need for multiple shell vials. Mixed cell lines stably transfected with host cofactors involved in the binding and entry of some enteroviruses (Super E-Mix ReadyCells) are commercially available (Quidel). These mixed cell cultures have been shown to be more sensitive for virus recovery from clinical samples compared to conventional tube or shell vial cultures with single cell lines.

Culture Using Other Living Hosts

Microorganism isolation, especially for some viruses, occasionally requires the inoculation of test specimens into animals and embryonated eggs. Viruses require intracellular replication, therefore inoculating a clinical specimen into cell lines (discussed previously), animal models or embryonated eggs, can aid in their isolation. As an example, several arthropod-borne viruses (arboviruses) that cause encephalitis can be isolated by inoculating the implicated specimen into suckling mice (Reynolds et al., 2017). Susceptible animal inoculation, such as animal models like the severe combined immunodeficiency mice, as well other rodents, have aided in the elucidation of unknown pathogens. Whereas, embryonated eggs are still the best culture medium for influenza viruses.

The ability to grow pathogens in animal models also provides scientists the opportunity to study the mechanisms of virulence and thus aid in the development of new diagnostic techniques, vaccines and treatments. A classic example of the use of animals as a vector to elucidate the etiology of infectious diseases is the discovery of *L. pneumophila* as the etiology of Legionnaires' disease. *L. pneumophila* was first identified by inoculating the clinical materials into susceptible guinea pigs (McDade et al., 1977). Guinea pigs have served as important animal models throughout microbiology's history. In fact, these aided in the development of Dr. Robert Koch's postulates of infectious disease etiology.

Table 3 Common cell cultures used in diagnostic microbiology.

Culture type	Characteristic	Cell line examples	Primary use	Comments
Primary	Diploid	Primary rhesus monkey kidney (rhMK)	Influenza, parainfluenza, enteroviruses	Endogenous virus infection, for example, SV-40; 1–2 passages only
Diploid cell lines	Diploid	Human diploid fibroblast MRC-5	Herpes simplex virus, cytomegalovirus, rhinovirus	Limited passage (50–70)
Established cell lines	Heteroploid	HEp-2, HeLa	Respiratory syncytial virus, adenovirus	Continuous passage; mycoplasma contamination

Measurement of Host Responses to Infection

Instead of detecting the presence of the microorganism, serologic tests measure the host's humoral immune response to a microorganism infection. Serologic tests are, in certain circumstances, the mainstay for diagnosis of certain infections whenever recovery of those organisms in culture is difficult or impossible. However, there is usually a lag between the onset of microorganism infection and the development of antibody to the organism. The presence of IgM specific antibodies is considered evidence of an active or recent infection, whereas the presence of IgG specific antibodies is evidence of a past exposure or chronic infection. Although IgM antibody appears relatively rapidly, IgM testing may be subject to interference by rheumatoid factors. For IgG testing, it is often necessary to obtain paired serum specimens, one taken during the acute phase of the disease and one taken during convalescence, to look for a rising titer of IgG antibody. A limitation on the use of serology as a diagnostic tool is that immunosuppressed hosts may be unable to mount an antibody response. In general, however, detection of specific antibody responses can be a very useful diagnostic approach in the postacute setting where causative organisms may be rare or completely absent. For example, serological testing for Lyme disease remains the mainstay of diagnostic evaluations because at the time many patients present, organisms have disseminated from the site of infection and are difficult or impossible to detect by direct methods based on culture or PCR (Theel et al., 2015).

Immunofluorescence Methods

Immunofluorescence techniques have been widely used in the past for detection of microorganism-specific antibodies and still have many applications. The common procedure used in a clinical serology laboratory is an indirect one. If present, the antibody in the serum specimen reacts with the microorganism-specific antigen, which was prefixed on a glass slide. After a wash step, fluorescein-conjugated immunoglobulin directed against the test serum species is overlaid on the slide. After washing, the slide is examined for specific fluorescence under a fluorescence microscope. This technique is still the primary choice for diagnosis of several virus infections, including Epstein–Barr virus and measles virus, in the majority of clinical virology or serology laboratories. However, fluorescence techniques are quite labor intensive and interpretation of the results is subjective; these techniques have, therefore, been gradually replaced by automatable and more objective serologic techniques such as EIAs.

Enzyme Immunoassays

EIAs have replaced radioimmunoassays in most diagnostic applications, and have become among the most widely used diagnostic methods in a clinical serology laboratory. In its most used format, the solid-phase EIA technique uses plastic microtiter plates or beads to which antigens are passively adsorbed. In a noncompetitive procedure, a test serum specimen is added. If present, the microorganism-specific antibody binds to the antigen. After washing, an enzyme-labeled immunoglobulin specific for the test serum species is added. After another wash step, a chromogenic enzyme substrate is added, and the color that develops is proportional to the amount of specific antibody present. The application of EIA serologic techniques for diagnosis of viral and rickettsia infections has expanded significantly. This assay is most frequently used in screening for immune status, such as in rubella testing, but they are also used as primary screening tests for infections due to HIV, HCV, HBV, and human T-cell lymphotropic virus.

Immunoblotting

The specificity of a serologic test is largely determined by the antigen used to capture the antibody in the direct test formats. An immunoblot (or Western blot) is one of the most specific serologic methods available. The general components of immunoblotting as used for immunodiagnosis with human sera include (1) electrophoretic separation of protein antigen on sodium dodecyl sulfate polyacrylamide gels, (2) electrophoretic transfer of the protein bands to a nitrocellulose or other support membrane, (3) blocking of free protein-binding sites on the membrane, (4) addition of the test serum, and (5) detection of the specifically bound serum antibodies. It is then possible to determine whether the patient's antibodies are directed against pathogen-specific or cross-reactive antigens. This additional level of analysis allows the discrimination of specific and nonspecific reactions. Immunoblotting has become a mainstay for confirming infection with HIV, HCV, and *B. burgdorferi* after initial positive EIA results.

Other Serologic Techniques

Other methods to detect immune humoral response to microorganism infections include agglutination and complement fixation assays. Agglutination reactions can be defined as the specific immunochemical aggregation of polystyrene (latex) particles coated with microorganism antigens that can be used to detect antigen-specific antibodies. Agglutination assays are simple to perform, and require only 15–30 min for completion, offering a useful alternative to EIA. This test has been used in the clinical serology laboratory for detection of rubella virus antibodies and quantification of rapid plasma reagin, which can be used as an indication of the therapeutic efficacy of syphilis treatment. Although the complement fixation test is still used in the serodiagnosis of several fungal infections, the system is extremely labor intensive, relatively insensitive, and will be gradually replaced with other formats. New techniques and formats in antibody testing have been emerging. A multianalyte profile (xMAP) allows simultaneous detection and differentiation of a panel of antibodies in a single reaction by using xMAP multiplexed technology (Luminex, Austin, TX, USA), which is highly desirable in clinical laboratories to provide a differential diagnosis of nonspecific conditions (Reslova et al., 2017).

Other Host-Response Determining Techniques

In addition to humoral immune responses, other host responses have been used in diagnostic microbiology field. For many years the tuberculin skin test (TST) has been used for screening *M. tuberculosis* infection. However, this test fails to discriminate between actual *M. tuberculosis* infection or vaccination with the Bacillus Calmette-Guérin (BCG) strain. Additionally, other nontuberculosis mycobacteria could also cause false-positive responses. Recently, interferon (IFN)- γ release assays (IGRA) have been developed to detect *M. tuberculosis* infection without cross-reactivity of the BCG vaccination. These tests measure the IFN- γ release following stimulation by specific *M. tuberculosis* antigens. There are three FDA-approved IGRAs manufactured by two companies, the T-SPOT.TB (Oxford Immunotec, Oxford, UK), the QuantiFERON-TB Gold (Qiagen, Venlo, Netherlands) and a newer version of the latter, the QuantiFERON-TB Gold Plus.

Sepsis is a life-threatening condition that requires early diagnosis and antimicrobial intervention. Hence, host response markers such as C-reactive protein (CRP) and PCT have been used to screen for sepsis. Nevertheless, blood culture remains the gold standard for isolation of bloodstream infection etiologies. C-reactive protein (CRP) is pentameric protein that aids in nonspecific host defense against inflammatory processes and cellular breakdown products by activating the classical complement cascade. CRP is one of the most sensitive acute-phase measures of inflammation, with concentrations rising to 1000-fold over baseline levels after such events as infection, trauma, surgery, burns, tissue infarction, and advanced cancer. Concentrations of CRP are generally higher in patients with bacterial infections relative to those with viral infections. However, high CRP levels may also be observed in individuals with influenza or mononucleosis. Overall, changes in CRP concentrations provide useful diagnostic information about the acuity and severity of a disease as the increase in CRP with inflammation occurs within 6–12 h and peaks at 48 h. However, caution must be taken when interpreting CRP results, as CRP elevations are nonspecific and the magnitude of CRP levels may be less pronounced in patients with liver disease (Gabay and Kushner, 1999). The diagnostic utility of CRP has also been evaluated for meningitis, but procalcitonin (PCT) has been shown to be more useful in discriminating between viral and bacterial meningitis (Alkholi et al., 2011). Recently, three host protein biomarkers, tumor necrosis factor-related apoptosis-inducing ligand, interferon gamma induced protein-10, and CRP, provided the diagnostic value to differentiate between bacterial and viral infections in children with lower respiratory tract infection or fever without source (van Houten et al., 2017).

Molecular Techniques in Diagnostic Microbiology

Identification methods based on biochemical phenotypic parameters can sometimes result in confusing or misleading results, especially when the number of features that can be analyzed is limited. Nucleic acid amplification technology has opened new avenues for the detection, identification, and characterization of pathogenic organisms in diagnostic microbiology. Molecular applications enhance the speed, sensitivity, and sometimes the specificity of an etiologic diagnosis. One good example is the detection and identification of pathogenic organisms directly from positive blood cultures. The promise of these techniques is the replacement of biological amplification—growth in culture—by enzymatic amplification of specific nucleic acid sequences, which is extremely useful to identify microorganisms that cannot be cultivated. The disadvantage, on the other hand, is the lack of recovered isolates for antimicrobial resistance determining. A full molecular procedure consists of specimen processing, nucleic acid amplification, and amplification product identification. Nucleic acid amplification techniques fall into three general amplification categories, which all share certain advantages over traditional methods, particularly for the detection of fastidious, unculturable, and/or highly contagious organisms (Table 4).

Nucleic Acid Extraction

A good specimen preparation is comprised of efficient target recovery, establishment of the integrity of nucleic acid targets, optimal removal of amplification inhibitors, elimination of components that affect other enzymatic substrates, and sterilization of potentially hazardous organisms (Thatcher, 2015). Numerous commercial methods and kits that are manual or automatic, with low or high throughput, are available for the extraction of microbial nucleic acids from a variety of clinical specimens. QIAamp MinElute Virus Kits (Qiagen, Inc., Valencia, CA, USA) have been demonstrated to effectively extract viral total nucleic acids from cerebrospinal fluid and respiratory specimens. Automated platforms such as the NucliSens easyMAG platform (bioMérieux, Durham, NC, USA) allow for high throughput processing, and high yield of quality total nucleic acids for clinical specimens and reduces the risk of contamination.

In Vitro Nucleic Acid Amplification Systems

According to the theoretical basis, *in vitro* nucleic acid amplification techniques can be placed into one of three broad categories, which all share certain advantages over traditional methods, particularly for the detection of fastidious, unculturable, and/or highly contagious organisms (Table 4). The first category is a target amplification system, which includes PCR, transcription-mediated amplification (TMA), nucleic acid sequence-based amplification (NASBA), strand displacement amplification (SDA), and helicase-dependent amplification (HDA), where many copies of the nucleic acid target are made. Among these amplification systems, PCR and PCR-derived techniques are the best developed and most widely used methods of nucleic acid amplification in the clinical setting. Semiautomated and automated systems have now been manufactured by Roche Molecular System, Inc. (Indianapolis, IN,

Table 4 Nucleic acid amplification methods.

Amplification method	Amplification category	Manufacturer (trade mark name)	Enzymes used	Temperature requirement	Nucleic acid target
Polymerase chain reaction	Target	Roche Molecular System, Inc. (Amplicor, Cobas [®]); Abbott Molecular (m2000); Cepheid (GeneXpert); Qiagen (Rotor-Gene Q MDx); Quidel (QuantStudio [™] Dx), etc.	Taq DNA polymerase	Thermal cyclers	DNA or RNA
Transcription-mediated amplification	Target	Bio-rad (Droplet Digital [™]); Thermo Fisher Scientific (QuantStudio [™] 3D)	Reverse transcriptase, RNA polymerase, RNase H	Isothermal	RNA or DNA
Nucleic acid sequence-based amplification	Target	Gen-Probe, Inc. (Aptima [®]) bioMérieux (NucliSens [®] , EasyQ [®])	Reverse transcriptase, RNA polymerase, RNase H	Isothermal	RNA or DNA
Strand displacement amplification	Target	Becton, Dickinson and Company (ProbeTec [™])	Restrictive endonuclease, DNA polymerase	Isothermal	DNA
Helicase-dependent amplification	Target	Quidel/BioHelix Corp. (IsoAmp [®])	Helicase, Taq DNA polymerase	Isothermal	DNA or RNA
Cycling probe technology	Probe	ID Biomedical, Vancouver, BC, Canada (CPT-strip)	RNase H	Isothermal	DNA or RNA
Ligase chain reaction	Probe	Abbott Laboratories, Abbott Park, IL, USA (LCx)	DNA ligase	Thermal cyclers	DNA
Hybrid capture system	Signal	Qiagen/Digene (Hybrid Capture)	None	Isothermal	DNA
Branched DNA	Signal	Siemens/Bayer Diagnostics, Emeryville, CA, USA (Versant [®])	None	Isothermal	DNA or RNA
Invader technology	Signal	Hologic/Third Wave Technologies (Invader [®])	Cleavase enzyme	Isothermal	DNA

USA), Abbott, Cepheid, Becton Dickinson and other companies for detection and/or quantification of several organisms including HIV, HCV, HBV, CMV, HSV, HPV, MRSA/*S. aureus*, *Clostridium difficile*, enterovirus, influenza, respiratory syncytial virus, group B *Streptococcus*, vancomycin-resistant enterococci, norovirus, *C. trachomatis*/*Neisseria gonorrhoeae*, *M. tuberculosis* and a variety of other organisms. In addition, numerous user-developed PCR-based DNA amplification techniques have been developed and applied to the detection of microbial pathogens, identification of clinical isolates, determination of antibiotic resistance, and strain subtyping. Commercially available products based on TMA, NASBA, HDA, and SDA are available from Gen-Probe, Inc., bioMérieux, BioHelix Corp. (Beverly, MA, USA), and Becton Dickinson and Company to detect and quantitate several microorganisms including *M. tuberculosis*, *C. trachomatis*, *N. gonorrhoeae*, MRSA, *C. difficile*, HIV, HCV, and enteroviruses (Table 4).

A second approach is probe amplification in which many copies of the probe that detects the target nucleic acid amplified after target-specific hybridization occurs. The ligase chain reaction (LCR) was the most widespread application of probe amplification in diagnostic microbiology until its withdrawal from the market (Table 4). When used following a target amplification method, such as PCR, LCR can be sensitive and useful for the detection of point mutations. Although convenient and readily automated, the main drawback of LCR was the difficult inactivation of postamplification products. The nature of the technique does not allow for the most widely used contamination control methods to be applied. Another technique in the system, cycling probe technology (CPT), which incorporates a unique chimeric DNA–RNA–DNA probe, has been designed to detect a specific sequence with *mecA* and *vanAB* genes for diagnostic use as a culture confirmation assay for MRSA and vancomycin-resistant enterococci.

The last amplification system is signal amplification, which is designed to strengthen a signal by increasing the concentration of label attached to the target nucleic acid. Unlike procedures which increase the concentration of the probe or target, signal amplification increases the signal generated by a fixed amount of probe hybridized to a fixed amount of specific target. The fact that signal amplification procedures do not involve a nucleic acid target or probe amplification is a theoretical advantage, because of lower susceptibility to contamination problems inherent in enzyme-catalyzed nucleic acid amplification. Sensitivity, however, compared to target nucleic acid amplification techniques, may be a limiting factor. Another limitation of signal amplification is background noise due to the nonspecific binding of reporter probes. Currently, three diagnostic companies have their signal amplification products available for molecular diagnostic purposes. The Digene Hybrid Capture System (Digene Diagnostics, Inc., Gaithersburg, MD, USA) is widely used to determine HPV infection in cervical swabs. Homogeneous Invader Technology (Hologic/Third Wave Technologies, Madison, WI, USA) is another signal amplification system, which is a powerful tool for genetic analysis of single nucleotide polymorphisms in both microorganisms and hosts.

Detection and Identification of Amplification Products

After amplification, the millions of target DNA copies that accumulate are invisible to the naked eye; therefore, an appropriate detection method is needed to “visualize” amplified DNA molecules. On the other hand, an additional identification system is critical to enhance both sensitivity and specificity of the PCR amplification procedure. Detection and identification of amplification products, or amplicons, has become a routine procedure in the molecular diagnostic laboratory. The classical means of detection and characterization of the PCR product was agarose gel electrophoresis, where sensitivity can be enhanced by Southern blot hybridization using DNA probes (Procop, 2007). Several user-friendly and rapid techniques have been adopted by molecular diagnostic laboratories, including direct sequencing, nucleotide microarray, mass spectrometry, and a “real-time” procedure. Due to the advancement of gene sequencing techniques, gene sequencing has become a powerful tool for molecular diagnostic laboratories. High throughput sequencing has reduced the cost and increased output for laboratories to identify and differentiate between closely-related bacteria and viruses. For example, gene sequencing is used to monitor HIV-1 responses to therapy and to identify genomic antiviral drug resistance mutations. In addition, gene sequencing has been applied to *Mycobacterium* spp. identification. The 16S rRNA gene has traditionally been the most frequently used target for differentiation of *Mycobacterium* species. However, the 65-kDa heat-shock protein (hsp65) has been shown to have more inter-species variability than the 16S rRNA gene and is, therefore, more useful for differentiating between closely-related species (Kapur et al., 1995; McNabb et al., 2004). Microarray technology is becoming more accessible for pathogen detection in the clinical setting. New devices are being developed that automate DNA extraction from patient specimens. In one example, the preliminary array technology included 11 different gram-negative, gram-positive, and yeast pathogens. These arrays successfully identified organisms collected from infected wound swab samples (Palka-Santini et al., 2009).

Arguably the biggest advance in PCR technology has been the development of closed system detection of amplification products which obviates the need for contamination-prone removal of amplification products. Early applications of PCR comprised PCR amplification followed by a separate identification of PCR products. With the introduction of a fluorescence resonance energy transfer, nucleic acid amplification, detection, and probe-specific confirmation of PCR products, no transfers of PCR products out of the reaction tube are required (Mackay, 2004). RT-PCR is closed and, therefore, avoids the important concerns of carryover contamination with previous amplification products. As a result of shorter thermocycling and simultaneous product detection, the turnaround time for results has also been significantly shortened. This technique is widely used to detect and quantify microorganisms and determine mutations in both microorganism and host genes. Real-time detection and characterization is also available in other *in vitro* amplification systems such as the Invader and NASBA systems.

Nongenomic Molecular Testing

Detection of Metabolic Products

The causal relationship between *Helicobacter pylori* colonization of the gastric mucosa and gastritis was first proposed in 1983 by Warren and Marshall, who received the Nobel Prize in physiology or medicine in 2005. *H. pylori* produces large amounts of urease which hydrolyzes urea to form ammonia and soluble carbon dioxide. Based on this, the noninvasive urea breath test (UBT) was developed. UBT allows screening for *H. pylori* infections without the need of an invasive procedure such as endoscopy or tissue biopsy. It also helps assessing the efficacy of eradication therapy (Wang et al., 2015). Either ^{13}C - or ^{14}C -labeled urea are used, but ^{13}C -labeled urea is preferred given that it is not radioactive as is ^{14}C -labeled urea. In brief, ^{13}C - or ^{14}C -labeled urea ingested by the patient is hydrolyzed to labeled CO_2 in the stomach. The labeled CO_2 is absorbed in the blood and exhaled. Patients breathe into a collection bag and the levels of labeled CO_2 are measured by mass spectrometry. Overall, UBT is a highly accurate and reproducible test with a sensitivity and specificity of 95% (Wang et al., 2015). One drawback of the test is the possibility of false positive results based on the presence of other urease producing pathogens in the stomach.

The application of volatile organic compounds (VOC) as biomarkers for the diagnosis of infectious diseases has been of great research interest. The use of VOCs for the detection of pulmonary infections caused by *M. tuberculosis*, *Pseudomonas aeruginosa*, and *Aspergillus fumigatus* have been evaluated. Several nicotinic acid metabolites produced by *Mycobacterium* species have been evaluated but shown unremarkable sensitivities and specificities (Sethi et al., 2013). This is also the case of other VOCs evaluated for detection of *P. aeruginosa* and *A. fumigatus*, since the same VOCs could be found in certain foods and thus cause false positive results (Sethi et al., 2013). Similarly, breath fungal secondary metabolite signature determined by thermal desorption-gas chromatography/mass spectrometry was used to diagnose invasive aspergillosis (Koo et al., 2014). When these metabolomic biomarkers are used in the clinical practice, we must remember the extreme heterogeneity of clinical illness, and strive for generalizable disease-defining diagnostics (Sweeney and Khatri, 2017). While detection of exogenous microbial volatile metabolites in the breath has opened up a new and exciting dimension of diagnostic research and development in infectious diseases, the daunting challenges to volatile diagnostic biomarker discovery and clinical development have to be kept in mind (Acharige et al., 2018).

Microbial Identification by Mass Profiling

Few developments in microbiological diagnostics have revolutionized the routine identification of microorganisms in clinical microbiology laboratories as matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS). Due to

its reliable capability to identify microbial pathogens in a rapid, high-throughput, accurate, and cost-effective manner, MALDI-TOF MS has become a gold standard for microbial identification. There are two commercially available MALDI-TOFs, the MALDI Biotyper® (Bruker Daltonics, Germany) and the VITEK MS® (BioMérieux, France). Both systems allow the phenotypic characterization of Gram-positive and Gram-negative bacteria, yeast, mycobacteria and mold. MALDI-TOF MS identification of microorganisms has an accuracy comparable with nucleic acid sequencing (Bizzini and Greub, 2010; Dhiman et al., 2011; Marko et al., 2012; Rychert et al., 2013). However, certain clinically relevant organisms cannot be distinguished by this method and require further testing for identification, as is the case of *Shigella* spp. and *E. coli* (Khot et al., 2012; Lan and Reeves, 2002). Another limitation of MALDI-TOF MS is the inability to discriminate among the members of certain bacterial groups/complexes (e.g., *Citrobacter freundii* complex and *Enterobacter cloacae* complex) (Richter et al., 2013).

Due to the high mortality risk of sepsis, it is imperative to identify microorganisms growing in blood cultures. Thus, both MALDI-TOF MS manufacturers have developed research only protocols to identify bacteria directly from positive blood cultures. Recently, the performance of these protocols in correct species level identification of monomicrobial blood cultures was shown to be >90% accurate (Chen et al., 2013). Nevertheless, these protocols are not useful to identify organisms in polymicrobial cultures. Research laboratories have also evaluated direct microorganism detection from urine samples. In brief, the urine sample is centrifuged to pellet the bacteria and then analyzed by the instrument (Demarco and Burnham, 2014; Ferreira et al., 2010; Inigo et al., 2016; Wang et al., 2013).

Besides microbial identification, research laboratories have explored the application of MALDI-TOF MS for microbial subspecies typing and antibiotic resistance marker detection (e.g., β -lactamases and carbapenemases) (Burckhardt and Zimmermann, 2011; Camara and Hays, 2007; Ghebremedhin et al., 2016; Hrabak et al., 2012; Idelevich et al., 2018). The recently developed direct-on-target microdroplet growth assay (DOT-MGA) allows rapid universal antimicrobial susceptibility testing using MALDI-TOF MS (Correa-Martinez et al., 2019; Idelevich et al., 2018). The ability of MALDI-TOF MS to type *Streptococcus pneumoniae* has also been explored, but serotyping of *Salmonella* by this method has been unsuccessful up to date (Kang et al., 2017; Nakano et al., 2015; Pinto et al., 2017). A recent study used quantitative proteomics to evaluate the host proteome response in septic patients secondary to community-acquired pneumonia. Bioinformatic analyses of differentially expressed proteins showed alteration in the cytoskeleton, cellular assembly, movement, lipid metabolism and immune responses in septic patients (Sharma et al., 2017).

Transcriptomics

Expression levels of specific RNAs have been associated with disease and infection. Utilizing transcriptomics, these RNAs can serve as biomarkers to monitor disease progression or aid in diagnosis when an organism cannot be recovered. Next generation sequencing and microarray technology has enabled the identification of these specific RNAs associated with infections and disease such as sepsis, HIV and tuberculosis (Correia et al., 2017). Using a series of RNA arrays on RNA extracted from pediatric patients with sepsis, Herberg et al. identified two host transcript RNA signatures which can distinguish bacterial from viral infection (Herberg et al., 2016). A further study demonstrated that the 2-transcript host cell signature can distinguish viral from bacterial diarrhea and it was influenced by the severity of symptoms (Barral-Arca et al., 2018).

Efforts to develop strategies for eradication of HIV-1 have intensified in recent years. However, while CD4⁺ T cell count and plasma viral load have been important markers of disease progression, their reliability has recently come into question as these markers do not reliably identify individuals on anti-retroviral medication with virological failure (Moore et al., 2008) and patients treated using immunotherapies that utilize recombinant viral proteins such as CAR T-cell therapy may produce false positive results (Ariza-Heredia et al., 2017; Laetsch et al., 2018). Recent reports have identified levels of miR-150 and miR-146b-5p in peripheral blood mononuclear cell and plasma as predictive of HIV/AIDS disease progression and therapy (Munshi et al., 2014).

In the case of *M. tuberculosis* infections, effective treatment regimens rapidly decrease the number of viable *M. tuberculosis* organisms in sputum, with the number of cultivatable bacilli typically reduced by approximately 10-fold within the first 1–2 weeks. However, because of the slow growth rate of *M. tuberculosis*, results of cultures for samples obtained early in treatment to monitor treatment efficacy will not be available in a timely manner (Mdivani et al., 2009). Bacterial clearance in TB patients receiving chemotherapy is important for a number of reasons, including early diagnosis of treatment efficacy, prevention of relapse due to incomplete cure, and as endpoints in clinical trials evaluating new tuberculosis medications (Bertholet et al., 2011). As a consequence, an mRNA RT-PCR assay analyzing antigen 85B mRNA from sputum samples has been developed as a test-of-cure for *M. tuberculosis* infections. This assay allows real-time, rapid monitoring of the response to anti-TB therapy and has a sensitivity and specificity of 85.2% and 88.6%, respectively. The antigen 85B mRNA RT-PCR assay data correlated clinically with resistance to anti-TB drugs, whereas the DNA PCR assay showed a high false-positive rate (Bertholet et al., 2011).

Molecular Diagnosis and Monitoring

Detection and Identification of Microorganisms

Over the past century, the identification of microorganisms has relied principally upon phenotypic characteristics such as morphology and biochemical characterization. Genotypic identification has emerged as an alternative or complement to established phenotypic methods. Broad-range PCR primers are designed to recognize conserved sequences in the phylogenetically informative gene of a variety of bacteria, and highly variable regions between the primer binding sites are amplified by PCR. The

amplified segment is sequenced and compared with known databases to identify a close relative. The most successful example is the rRNA gene sequence-based microbial identification system, which includes the extraction of nucleic acids, PCR-mediated gene amplification, sequence determination, and computer-aided analysis.

The growing availability of next-generation sequencing has allowed for whole-genome sequencing of bacteria, which has identified additional PCR targets to identify organisms, detect virulence factors, antibiotic resistance markers, and for molecular genotyping. The time, effort, and cost associated with sequencing data analysis were previously major limitations of using sequencing technologies in a clinical setting. However, next generation platforms such as Ion PGM (Life Technologies) and the MiSeq (Illumina) have decreased sequencing costs while simultaneously increasing efficiency and improving turnaround times (Didelot et al., 2012).

Microorganism Quantification

Quantification of nucleic acid targets has become desirable in the clinical practice to monitor therapeutic responses and provide prognostic information for infectious diseases. The task of quantitative amplification has been problematic since the amplification techniques yield products in an exponential manner until a plateau is reached; any factor interfering with the exponential nature of the amplification process would thereby affect the result of the quantitative assay. To overcome this problem, a competitive RT-PCR assay was developed based on coamplification of an internal competitor with the target sequence. Currently, quantification of microorganism load is based primarily on (1) target amplification, which includes both PCR- and NASBA-based techniques, and (2) branched DNA-based signal amplification. Commercially available kits are available to make it possible for many clinical laboratories to carry out quantitative analysis. RT-PCR-based systems are widely being used for microorganism quantification in clinical microbiology services. The unique characteristic, simultaneous, cycle-by-cycle detection of PCR products has made possible a rapid, high-throughput quantification of nucleic acid sequences (Mackay, 2004). Several RT-PCR systems have been successfully used to manage infections caused by HBV, HCV, HIV, CMV, Epstein-Barr virus, and BK virus.

Digital PCR (dPCR) represents a relatively new method of nucleic acid quantification in microbiology. Like conventional PCR and RT-PCR, dPCR involves amplification of target nucleic acids using fluorescent probes, however the reaction is randomly distributed into thousands of partitions in such a way that ideally, each partition only contains one target molecule to be amplified. Depending on the platform, partitions can be in the form of microwell plates, capillaries, oil emulsions, or chip arrays. After amplification, absolute quantification can be achieved by counting the number of positive (fluorescent) and negative partitions (no fluorescent) and calculating Poisson's distribution. Digital PCR provides an advantage over qPCR in that it allows for absolute quantification without calculation of CT values and standard curves. In addition, dPCR also allows for detection of rare alleles and clinical samples in that contain low amounts of nucleic acids body fluids or tissues (Kuypers and Jerome, 2017). Currently, dPCR has been applied to detection of HPV in tumors of patients with head and neck cancers (Jeannot et al., 2016), detection and quantification of HIV viral load, CMV and surveillance for antibiotic and antiviral resistance (Luo et al., 2017; Taylor et al., 2015).

Syndromic, Multiplex Testing

Certain infectious diseases present themselves with similar or nonspecific clinical manifestations, thus making an accurate diagnosis challenging. Traditionally, different methods of detection are employed for detecting different pathogens responsible for these similar syndromes. This requires special media, equipment, and sophisticated facilities. Much effort has gone into developing syndromic, multiplex molecular techniques that are more effective and easier to perform within the diagnostic laboratory. By utilizing numerous primers within a single reaction tube, nucleic acid fragments from multiple targets can be amplified at the same time, thus allowing screening of a clinical specimens for several probable pathogens. Nevertheless, the ability to screen for large numbers of potential etiologies limit detection efficiency. Several syndromic panels commercially available for detection and simultaneous identification of common pathogens involved in respiratory, gastrointestinal and blood infections, respectively. Additionally, some panels also detect antimicrobial resistance markers which can aid in optimal selection of antimicrobial treatment.

There are several FDA-cleared gastrointestinal panels available in the United States. The xTAG Gastrointestinal Pathogen Panel (Luminex, Austin, TX, USA) was the first FDA-cleared multiplex PCR for detecting gastrointestinal pathogens (Dunbar et al., 2013). This panel constitutes of 15 gastrointestinal pathogens, including bacteria, viruses and parasites. It has a turnaround time of <5 h, whereas the FilmArray® (BioFire Diagnostic, Salt Lake City, UT, USA) can detect 22 targets (bacteria, viruses and parasites) in a total run time of about 1 h. The Verigene® Enteric Pathogens Nucleic Acid Test, which was recently acquired by Luminex, targets nine analytes (bacteria and viruses). BioCode Gastrointestinal Pathogen Panel (Applied BioCode, Santa Fe Springs, CA, USA) is another recently FDA-cleared gastrointestinal panel testing for 17 most common bacteria, viruses, and parasites in stool with high throughput BioCode MDx-3000 molecular system. The FDA-cleared respiratory panels include the FilmArray® respiratory panel (20 bacterial and viral targets), Verigene® Pathogens Flex test (16 targets, bacteria and viruses) and the xTAG® Respiratory Viral Panel (viral only). As for the meningitis/encephalitis panels, these are offered by the FilmArray® (14 targets including bacteria, fungi and viruses) and the AllPlex™ Meningitis (Seegene, Rockville, MD, USA) (18 bacteria and viruses). One limitation of these panels is that since they target microbial nucleic acid (DNA or RNA), they cannot distinguish between viable, replicating organisms responsible for disease from traces of nucleic acid (Binnicker, 2015).

Table 5 Food and Drug Administration-cleared bloodstream infection rapid diagnostic methods.

Test manufacturer	Detection method	Analytical time	Specimen	Comments
FilmArray® Blood Culture Identification (BCID) Panel (BioFire Diagnostics)	Nucleic acid amplification	1 h	Positive blood culture	Identifies Gram-positive and Gram-negative bacteria, yeast and detects 3 resistance markers
VERIGENE® (Luminex Corporation)	Microarray	2.5 h	Positive blood culture	Identifies Gram-positive and Gram-negative bacteria, and detects 6 resistance markers
Accelerate PhenoTest™ BC Kit (Accelerate Diagnostics)	FISH	1.5 h (ID) 7 h (AST)	Positive blood culture	Identifies bacteria and 2 <i>Candida</i> spp. Performs phenotypic antimicrobial susceptibility testing (AST) for bacterial targets
ePlex® (GenMark)	Nucleic acid amplification	1.5 h	Positive blood culture	Gram-positive panel: 20 bacteria, 4 resistance markers Gram-negative panel: 21 bacteria, 6 markers Fungal panel: 15 targets

Due to the urgency in determining the etiology of a bloodstream infection, these companies have also developed multiplex PCR assays that allow this. Besides PCR, other molecular techniques that enable multiplex testing of positive cultures have been developed and are summarized in Table 5.

The Accelerate PhenoTest system (Accelerate Diagnostics) utilizes gel electrofiltration and fluorescence in situ hybridization FISH for identification but besides identification, it also performs antimicrobial susceptibility testing (AST) (Ramanan et al., 2018). The T2Dx instrument (T2Biosystems, Inc., Wilmington, MA, USA) is FDA-approved for bacteremia and candidemia. Their assay combines nuclear magnetic resonance and PCR to directly detect and define the organisms from whole blood samples with a limit of detection as low as 1 cfu/mL of whole blood (Clancy and Nguyen, 2018).

Rapid, On-Demand, and Point-of-Care Testing

Rapid provision of results can facilitate better clinical decision-making, improved patient adherence, and greater patient satisfaction, all of which lead to improved clinical outcomes with wider patient, operational, economic, and societal benefits. For example, early and accurate diagnosis of the central nervous system infections has been critical to clinical intervention in terms of choosing chemotherapy and predicting prognosis. Early diagnoses of meningitis improves patient care and in return decrease the costs of care by reducing hospital stay length and antibiotic use. Similarly, direct detection of *Streptococcus pyogenes* antigens in throat swabs can improve the treatment of pharyngitis by detecting the majority of streptococcal infections while the patient is still in the office. Detection of specific nucleic acids is more sensitive but also less rapid and more expensive than antigen detection.

Technology advances in molecular microbiology now enable a wide range of diagnostic tests to be provided at the point of care. The GeneXpert® Dx diagnostic system (Cepheid) is an important new development in the field of molecular diagnostics. It automates all of nucleic acid diagnostic steps in a disposable, microfluidic cartridge and is the first real-time PCR system that can be used to provide “real-time service” (Boehme et al., 2010; Xie et al., 2017). Although it was approved by the FDA as a moderately complex test, it is simple enough to be performed reliably by individuals without a background in nucleic acid diagnostics. Sample preparation reagents and samples are all that are required to add to the cartridge by the user. It has independently controlled and operated analysis modules that facilitate testing of individual samples in a random-access mode (Fig. 2A). The complete automation and rapid result capability of the GeneXpert make it uniquely suited for on-demand and point-of-care testing for testing respiratory specimens for Influenza, MRSA surveillance, virus and stool samples of suspected *C. difficile* patients.

The Alere™ i (Fig. 2B) is a small isothermal nucleic acid amplification platform that allows for the qualitative point-of-care detection of infectious diseases. For example, the Alere™ i Influenza A & B panel produces flu results in <15 min making it the first FDA-cleared, CLIA-waived molecular device used in point-of-care setting (Wang et al., 2018). The Cobas® Liat™ Analyzer (Fig. 2C) automates all nucleic acid testing processes, including reagent preparation, target enrichment, inhibitor removal, nucleic acid extraction, amplification and real-time detection. The machine has a very small foot print and is built with a touch screen, eliminating the need for an additional neighboring computer, and reports results in 20–60 min depending on the test (Ling et al., 2018). Quidel/Biohelix has developed several Helicase-dependent isothermal amplification diagnostic assays (AmpliVue® series) (Fig. 2D). These assays do not require any instrument and can be performed at room temperature. Quidel AmpliVue assays available include *C. difficile*, group A and B streptococci, and HSV 1 and 2.

Laboratory Automation

Historically, microbiology laboratories have been less automated than other clinical laboratories however, technological advances have brought on availability of more automated devices for the busy clinical microbiology laboratory. Different levels of

Fig. 2 Rapid, on-demand, and point-of-care testing. (A) The Xpert[®] EV assay (Cepheid) comes as a unit dose, self-contained kit (Xpert enterovirus self-contained cartridge) run on the GeneXpert[®] Dx diagnostic system (<http://www.cepheid.com/us/cepheid-solutions/systems/genexpert-systems/genexpert-xvi>). The only extra equipment required is a pipette that can deliver 140 mL of Lysis Reagent and sample into the cartridge. The whole test takes <5 min of hands-on time, and results are available in about 2.5 h. (B) The Alere[™] i Influenza A & B panel is a point-of-care tests that offers results in as few as 15 min (<https://www.alere.com/en/home/product-details/alere-i-influenza-ab.html>). (C) The Cobas[®] Liat Analyzer[™] automates molecular testing for influenza A and B (<https://diagnostics.roche.com/us/en/products/systems/cobas-liat-system.html>). The machine has a small footprint and 20–60 min turn-around time enabling its use for point-of-care diagnostics. (D) The Quidel AmpliVue[®] kits are available for instrument-independent, room-temperature molecular diagnostics (<http://www.quidel.com/molecular-diagnostics/amplivue-products>).

automation can be incorporated each phase of testing, from sample processing to total lab automation (TLA). In the preanalytical phase, the Previ[®] Isola (bioMérieux; Fig. 3A) and the Walk-Away Specimen Processor (WASP[®]; Fig. 3B) are examples of automatic specimen processing and plate inoculation platforms currently on the market. The Previ[®] Isola plates, streaks, and labels as many as 180 plates per hour. The Wasp is a comprehensive system which encompasses all aspects of liquid specimen processing including plate streaking, slide preparation, and enrichment broth inoculation. In the analytical phase, automated antibiotic susceptibility testing platforms including Vitek[®] (bioMérieux), MicroScan[®] (Siemens), Phoenix[™] (BD) systems and The Sirscan2000 automatic by i2a incubate, read and publish results (Fig. 3C). TLA systems such as the BD Kiestra[™] (BD; Fig. 3D) and The Wasp Lab (Copan) include specimen processing, incubation in aerobic and CO₂ atmospheres, and digital imaging of plates. Automation has allowed for standardization, more rapid results, reduction in labor costs and improved safety (Croxatto et al., 2016; Dauwalder et al., 2016; Novak and Marlowe, 2013).

Concluding Remarks

Diagnostic microbiology has been developing new methods to rapidly detect and accurately identify implicated microorganisms in test specimens through a variety of techniques. Technologic changes have made significant progress in the various areas including bacteriology, mycology, mycobacteriology, parasitology, and virology during the last two decades in the field of diagnostic microbiology. The physical structure of laboratories, staffing patterns, work flow, and turnaround time have all been influenced

Fig. 3 (A) The Beckton Dickinson Kiestra™ InoqulA™ (D) is a fully automated, high throughput machine that processes both liquid and solid samples (photo courtesy of Paul Bourbeau). The InoqulA™ system fully integrates with additional products from the BD Kiestra™ line which automates incubation, reading, identification, and susceptibility of samples (<https://www.bd.com/en-us/offers/capabilities/lab-automation/bd-kiestra-inoqula-plus-specimen-processor>). (B) The bioMérieux Previ® Isola provides clinical laboratories with an automated means to quickly and accurately identify and perform antimicrobial susceptibility testing (<http://www.biomerieux-diagnostics.com/previ-isola>). (C) The Walk-Away Specimen Processor (WASP®) by Copan encompasses all aspects of liquid specimen processing including plate streaking, gram slide preparation, and enrichment broth inoculation (<http://www.copanusa.com/products/automation/wasplab/>). profoundly by these technical advances. The implementation of nucleic acid amplification-based molecular techniques provides complementary, rapid, and on-demand diagnosis services. These changes will continue, and lead diagnostic microbiology inevitably to be a modern discipline, which will be equipped to face inevitable challenges in the future.

Glossary

Amoebas Protozoa that move using pseudopods.

cAMP, cyclic AMP, adenosine 3'/5'-monophosphate An ATP derivative that is most commonly used as an intracellular intermediate for cellular responses to hormones and other extracellular signals.

Chemoattractant Organic or inorganic substance that induces directional cell movement in motile cells.

Chemotaxis Directional cell movement toward or away from chemicals in the environment.

Culmination The process of forming a fruiting body.

Cytokinesis Contraction and division of cytoplasm to form two identical daughter cells each containing one nucleus.

Dictyostelids The order of cellular slime molds, also known as social amoeba.

differentiation The process by which a single cell becomes more specialized, or a group of cells start to differ from each other.

Diploid The state of cells containing two copies of each chromosome.

Fruiting body A structure formed to carry spores aloft for improved preservation and dispersal.

Homologous recombination Genetic recombination event involving physical rearrangement between two strands of DNA.

Homothallic Refers to a species whose members can mate with any other individual, as opposed to heterothallic where only members of opposite sex or mating type can mate.

Parasexuality A phenomenon where two cell nuclei merge without any sexual process and the chromosome count is doubled.

Phagocytosis The cellular process of engulfing solid particles in membrane-bound compartments to form a phagosome.

Phototaxis Directional cell movement toward or away from a light source.

Thermotaxis Cell movement toward or away from a heat source.

Transformation Altering the genetics of a cell by introducing foreign DNA.

Abbreviations

ALC	anterior-like cell
asp	aspartate
cAMP	cyclic AMP
cAR	cAMP receptor
PdsA	phosphodiesterase
PIP2	phosphatidyl inositolbisphosphate
PIP3	phosphatidyl inositoltrisphosphate
PKA	cAMP-dependent protein kinase
REMI	restriction enzyme-mediated integration
SDF	spore differentiation factor

Defining Statement

Dictyostelid social amoebae present a useful model for the study of cell biology in the context of free-living single cells and during multicellular development.

Taxonomy, Evolution, and Ecology

All members of the Dictyostelid taxonomic group grow as free-living amoebae that feed on bacteria in decaying vegetation in the soil. When the food source is depleted they enter one of three different development programs, the most spectacular of which is the formation of the multicellular fruiting body.

[☆]*Change History:* (1) New sections on social evolution and “farming”. (2) Revised section on the genome and genomics. (3) Revised and new sections on cell biology. (4) Revised section on chemotaxis. (5) Revised section for prestalk cell and stalk formation. (6) Revision of section on intracellular mechanisms of cAMP in culmination.

This article is an update of C. Scott, P. Schaap, Dictyostelium, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 606–616.

Of the 100 or more known species in the group, *Dictyostelium discoideum* is the most extensively studied. When *D. discoideum* cells starve, cells start to secrete pulses of cyclic AMP (cAMP), a molecule that regulates events inside the cell in most other organisms. When receiving a cAMP pulse, neighboring cells migrate toward the signal source in a process called chemotaxis. In turn these cells secrete their own cAMP pulse. The pulse propagates as a wave through the cell population, coordinating the movement of up to 1 million cells to come together to form a packed mound of cells. Subsequent signaling between cells directs their differentiation into different cell types and directs cell movement to form a fruiting body. This consists of thickly walled spores within a spore head lifted up by a stalk that is formed from cellulose-encased stalk cells. Additional ancillary structures support the spore head and form a disc of stalk cells at the base, from which the species gets its name, to anchor the stalk to the substratum. An intermediate, motile “slug” stage allows the whole multicellular structure to relocate before fruiting body formation and spore dispersal to a more nutrient-rich habitat (Fig. 1).

In addition to fruiting body formation, amoebae have two alternative responses to starvation. Some species can encyst as individual cells to form dormant microcysts (Fig. 2). Microcysts are less dehydrated than spores and have a thinner two-layered cell wall instead of the thick three-layered spore coat. Alternatively, cells can form sexual macrocysts. This requires the presence of cells with opposite mating types, of which there are three, although homothallic mating is also common. Macrocyst formation begins when two cells fuse to form a zygote. The zygote then attracts other starving cells and cannibalizes them. Eventually, the zygote synthesizes a highly resistant thick cell wall and enters a long period of dormancy. Macrocysts are more commonly formed under dark and wet conditions that are not favorable for fruiting body formation.

Molecular taxonomy based on gene or protein sequence comparisons place Dictyostelid within a supergroup known as Amoebozoa. This group is separate from, but closely related to, the opisthokonts, the group containing the animals and fungi. Further phylogenetic studies subdivide the Dictyostelids into four major divisions. Species in groups 1–3 generally form small clustered and branched fruiting structures from a single aggregate (Fig. 3). Group 4, species usually form a single robust unbranched structure. Most species in groups 1–3 can form microcysts, whereas group 4 species have lost this survival strategy. The sexual cycle,

Fig. 1 The life cycle of *Dictyostelium discoideum*. Unicellular amoeba aggregate to form mounds in response to starvation. Within the mounds the cells begin to differentiate into prestalk and prespore cells and the mound morphs into a migratory slug. When suitable conditions for spore dispersal are found, the slug sits down and fruiting body formation commences. Reproduced from Scott, C., Schaap, P., 2009. Dictyostelium. In: Schaechter, M. (Ed.), Encyclopedia of Microbiology. Oxford: Elsevier, pp. 606–616.

Fig. 2 Surviving starvation. Amoebas can adopt one of three survival strategies when faced with starvation. Solitary amoeba can encapsulate individually to form microcysts, two amoebas can fuse to form a zygote, which then attracts other cells to form a sexual macrocyst, or amoebas can aggregate to form fruiting bodies, where part of the cells die to form a stalk and the others survive as highly resistant spores. Reproduced from Scott, C., Schaap, P., 2009. Dictyostelium. In: Schaechter, M. (Ed.), Encyclopedia of Microbiology. Oxford: Elsevier, pp. 606–616.

resulting in macrocyst formation, occurs in all groups. Group 4 species also stand out by their use of cAMP as the chemoattractant for aggregation, with a variety of other compounds being used by the other groups (Fig. 3).

Dictyostelids have been found all over the world and adapted to many environmental conditions. Forest soils contain the largest variety of species, but also cultivated soils and even deserts harbor at least some species. Some species seem happy to grow under almost any conditions, coping with a wide variety of changes in humidity and altitude. Cosmopolitan species grow almost anywhere and include the species *Dictyostelium mucoroides* and the exquisite *Polysphondylium pallidum*. However, others are far more particular about their choice of residence, with disjunct species, including *D. discoideum*, being widely geographically distributed, but found in similar habitats and climates. Generally speaking, the tropics contain the highest number of species and species variety decreases as latitude and altitude increase.

The cooperative behavior seen in the dictyostelid social amoebae offers a powerful molecular cell model to study the mechanisms of social evolution. At the heart of its social interaction is the process of determining whether each individual amoeba differentiates into a viable spore or a dead stalk cell. While benefiting the population by forming the fruiting body, stalk formation is detrimental to the survival of the individual cell. So how does this altruistic behavior become evolutionary stable, and why do cells not “cheat” by always forming into spore cells? Such “cheater” mutants can be isolated in the laboratory, however strains isolated from the wild always develop fruiting bodies with stalks, although they can exhibit genetic variation in the ratio of spore to stalk cells. Such studies have shown that this altruistic behavior combines elements of an individual competitive drive for efficient spore formation, coercion of other cells to form stalk and the mechanism of kin selection, in which loss of individual cells is balanced by increased survival of a genetically closely related population. This latter effect requires an ability to distinguish relatedness, and an allo-recognition system has been discovered that requires the *TgrB-C* genetic locus that encodes a family of cell-cell adhesion proteins capable of sorting cells of different strains during aggregation.

In addition to interactions between *Dictyostelium* cells, the interaction with soil bacteria is more complex than simple predation of a food source. Some *Dictyostelium* strains have been found to be “farmers” with an ability to accumulate bacteria in the fruiting body to disperse both amoebae and bacterial cells. This is an endosymbiotic relationship, with bacteria present within spore cells. One interesting interaction is seen with strains of Burkholderia bacteria, which are not a food source themselves, but induce farming of other bacteria species. Consequently, Burkholderia confer advantages when spores are dispersed into environments that are low in bacteria, and hence provide benefit for survival. In the wild only about a third of *Dictyostelium* isolates naturally farm, however it would appear that this is dependent on the propensity for the cells to secrete the protein Discoidin, which protects bacteria and allows entry into the cell. However, not all bacteria associations are beneficial, for instance the bacterium *Mycobacterium marinum* will infect *Dictyostelium* by hijacking the cells machinery for autophagy, a mechanism that normally surrounds cell debris for degradation. This is a good model for infection of human lung cells with *Mycobacterium tuberculosis*, the cause of TB.

Fig. 3 Trends in the evolution of morphology. Cartoon representation of the distribution of morphological characters across the molecular phylogeny. Spore size and the position of polar granules in the spores shows strong group-specific trends. Sexual macrocysts are formed by multiple species in each group, but microcysts are no longer formed in group 4. Species in groups 1–3 usually form multiple fruiting bodies from a single aggregate that often carry side branches, while species in group 4 tend to form large solitary and unbranched structures. They also form cellular supports or basal discs to hold up the stalk. Only a subset of species in group 3 forms crampon-like supports. In contrast to Group 4 species, none of the species in groups 1–3 use cAMP as a chemoattractant. Reproduced from Scott, C., Schaap, P., 2009. Dictyostelium. In: Schaechter, M. (Ed.), Encyclopedia of Microbiology. Oxford: Elsevier, pp. 606–616.

Genomics

The *D. discoideum* Genome

The whole *D. discoideum* genome sequence was published in 2005. It is haploid, 34 Mb in size and arranged over six chromosomes. This makes it about 95 times smaller than the human genome. However, it contains approx. 12,750 protein coding genes, giving it a much greater gene density than the human genome, with ~60% of the number of human genes in 1% of the space. Due to its compact genome, genes have relatively small intergenic regions and introns, although still 11% of sequence in the *Dictyostelium* genome is of low complexity, much of which is present as nucleotide repeats. Such repeats can be found in protein coding regions, such as the long sequence stretches of glutamine (polyQ) and asparagine (polyN). The genome complement is completed by 490 non-coding RNA genes, clusters of transposable elements, the array of rRNA genes with the rDNA element and its palindromic extrachromosomal 88-kb derivatives present at ~100 copies per nucleus; and the 56 kb mitochondrial genome. The genomes of three other Dictyostelid species have also been completely sequenced covering all 4 phylogenetic groups: *D. fasciculatum* (group 1); *Polysphondylium pallidum* (group 2), and *D. lacteum* (group 3). dictyBase is an online genomic resource that links the genomic sequences of the 4 dictyostelid species to descriptions of each gene, associated mutant phenotypes, current bibliography and RNA-seq data.

The genome nucleotide composition of *D. discoideum* is very biased with an A/T enrichment of approx. 70% within coding sequences and approaches 90% in non-coding regions. Each chromosome has a telocentric centromere (i.e., located near one end of the chromosome), which is characterized by a single cluster of repeats rich in DIRS (Dicty intermediate repeat sequence) elements. *Dictyostelium* does not possess conventional telomeres, but instead the ends of chromosomes are associated with partial copies of

the rRNA element. Recombination between DIRS and rDNA elements on Chromosome 2 are thought to be responsible for the inverted duplication of 608 genes seen in AX4 laboratory strains.

The *Dictyostelium* genome possesses nearly all of the gene families found in the human genome. These include 60 G-protein coupled receptors (GPCRs), 285 protein kinases and 152 transcription factors. Some protein families have more members in *Dictyostelium* than humans, such as the Frizzled receptors and polyketide synthase genes, which at greater than 40 is the largest number known in any organism. Interestingly, it also contains a number of xenologues, genes horizontally transferred from bacteria. These include histidine kinases, 2-component signaling proteins and genes for synthesis of cyclic nucleotides, including cAMP and dicyclic-GMP.

Classical genetic procedures and linkage analysis in *D. discoideum* remains problematic due to the very slow and infrequent germination of sexual macrocysts. However, *D. discoideum* can also undergo a parasexual cycle whereby two haploid cells can fuse together to form a diploid cell, which contains the chromosomes of both parents contained within a single nucleus. This occurs with a frequency of about 1 per 30,000 amoebae. The resultant diploid cells are relatively stable and divide as normal, producing diploid progeny. However, occasionally the diploids lose a copy of each chromosome and revert to a haploid condition with a random mixture of chromosomes from the parental strains. Diploid cells can be selected by using parental strains with complementary markers. Thus, the parasexual cycle of *Dictyostelium* can be used to generate multiple knockout mutants by recombining several existing mutations.

Protocols for genetic transformation of *D. discoideum* were established in the mid-1980s and have now been expanded into a broad repertoire of techniques. Genes can be expressed from constitutive and inducible promoters with a variety of tags for visualization of proteins in living cells, or purification of proteins and protein complexes. *Dictyostelium* multicellular structures are transparent and are therefore fully amenable to all microscopic investigation. By using these approaches, *Dictyostelium* has become a paradigm for studying cytoskeletal remodeling in living cells during chemotaxis, cell division, and vesicle trafficking.

Genes can be disrupted or replaced with mutant alleles using homologous recombination, which works very efficiently in *Dictyostelium*. Because development is separated from growth and cell division, most developmentally regulated genes are not essential and their mutations can be investigated for their effect on the developmental programme. This has opened up *Dictyostelium* as a powerful molecular genetic tool for studying gene function. Multiple gene deletions can be achieved by consecutive transformations using different selectable markers or by reiterated excision of the same selectable marker by cre-lox recombination.

Creation of random insertion mutants was more problematic until the application in *Dictyostelium* of the restriction enzyme-mediated integration (REMI) method. This enables efficient screens for genes that confer specific phenotypes. Briefly, a restriction enzyme digested plasmid carrying a resistance cassette is introduced into *Dictyostelium* cells along with a restriction enzyme that generates cuts in the genome with sticky ends that are compatible with those of the digested plasmid. The cell DNA ligases repair the cuts, occasionally inserting the plasmids. Resistant cells are recovered, cloned and inspected for mutant phenotypes. Plasmid rescue or inverse PCR methods can be used to identify the genome insertion site. REMI can be adapted for population screens for drug sensitivity or cell competition. A high throughput REMI method (REMI-seq) that incorporates next-generation sequencing to simultaneously screen 1000 s of REMI clones is making a large impact on the number of *Dictyostelium* mutants available for study. The current Genome-wide Dictyostelium insertional mutant (GWDI) bank contains over 5000 gene insertions.

Cell Biology

The combination of being a haploid, free-living unicellular organism and its advanced genomics makes *Dictyostelium* a powerful model for many areas of cell biology, and a useful workhorse for the study of human diseases. Much of this cell biology hinges on control of the actin cytoskeleton, which is utilized in a plethora of functions from including cell motility, membrane trafficking and cytokinesis, often using the same proteins in different ways. There is an extensive body of work in isolating, cloning and study of the regulators of Actin polymerization and its reverse.

Feeding on bacteria, *Dictyostelium* cells have very active phagocytosis, and can engulf relatively large particles, providing a good basis for genetic screens for regulation of phagocytosis. A key decision that the cell must make is the balance between deploying actin polymerization for phagocytosis or cell motility, as these processes appear to be mutually exclusive. Interestingly, factors from bacteria such as folate can both act as a chemoattractant to direct cell movement towards bacteria, but when the cells make contact with the bacteria, they switch into phagocytosis.

Most wild-type cells can only grow by phagocytosis of bacteria, however the commonly used laboratory strains have been selected for the useful property of growing in bacteria free liquid medium. This process is known as macropinocytosis as the cells have gained the ability to engulf large volumes of liquid. The gene responsible for this unusual ability has been cloned, and is the *Dictyostelium* orthologue of Neurofibromatosis type I, NF1, a gene responsible for one of the most common human genetic disorders, and causes tumours of the nervous system. NF1 is a negative regulator of the oncogene ras, and in *Dictyostelium* leads to misregulation of actin polymerization during phagocytosis.

Dictyostelium also offers opportunities for modeling other aspects of human disease. The DNA repair mechanisms of *Dictyostelium* have close similarities to those seen in mammalian cells, and offers a good opportunity to study the processes that monitor and fix damaged DNA. Mutant screens have been used successfully to screen for resistance to commonly used drugs, such as the anti-cancer drug cisplatin, and the mood stabilizers lithium and valproic acid. This has provided new evidence for the mechanism of action of these drugs.

The Developmental Programme of *D. Discoideum*

Upon starvation, *Dictyostelium* enters its developmental programme. For simplicity this can be divided into three phases: aggregation, multicellular development and culmination (Fig. 4).

Aggregation

Although starvation is the primary trigger for commencing development, quorum-sensing factors ensure that the developmental program only commences if there are sufficient cells. These factors down-regulate genes needed for cell growth and induce low expression of aggregation genes, such as cAMP receptor cAR1 and adenylyl cyclase ACA. During aggregation cAMP is synthesized by ACA, which is regulated by cAR1 that is coupled to heterotrimeric G-proteins. Activation of cAMP receptors initially stimulates cAMP synthesis, but as the receptor saturates, it desensitizes and ACA activity drops. Extracellular cAMP is rapidly broken down by the cAMP phosphodiesterase PdsA, allowing the receptor to reactivate and become sensitive to further cAMP stimulation. This cycle results in the production of cAMP pulses in the nanomolar concentration range (Fig. 5). In addition to triggering chemotaxis and cell aggregation, the cAMP pulses strongly accelerate the expression of aggregation genes, causing cells to aggregate to form the multicellular mound after 8–10 h. cAMP pulses also induce competence, that is, components of novel signal transduction pathways for the gene expression events that occur after aggregation.

A key function of extracellular cAMP pulses is to act as a chemoattractant to bring cells together to form the mound, initiating multicellular development. At its simplest level, chemotaxis involves detection of a gradient of chemoattractant and translation of this external gradient into an internal gradient that causes directional movement. However, the molecular mechanisms that underlie chemotaxis are extremely complex and an area of intense study both in *Dictyostelium* and for cell biology in general. *Dictyostelium* cells move by protruding pseudopods in the direction of movement in a process that requires cARs and the G-protein G α 2. Pseudopods are enriched in filamentous actin (F-actin), which provides rigidity to the cell cortex of the extending pseudopod. Pseudopods tend to form close to the base of the previous pseudopod, and regions of the F-actin cytoskeleton are enriched in a number of major signaling proteins, including ras proteins and the downstream effector PI3-kinase, the enzyme that generates phosphatidyl inositol trisphosphate (PIP₃). These in turn promote actin polymerization (Fig. 6(a)). Away from the extending pseudopod, the back of the cell is enriched in both the PIP₃ phosphatase, PTEN, and myosin. Myosin both cross-links F-actin and squeezes the back of the cell (Fig. 6(b)). Time-lapse video-microscopy often detects the rapid protrusion of membrane, blebbing, in a mechanism that requires myosin, but occurs in advance of actin polymerization, suggesting that actin polymerization occurs relatively late in the pathway controlling chemotaxis. Indeed, cells that lack the ability to generate PIP₃ also undergo chemotaxis. Current thinking views PIP₃ synthesis as one component of local excitable network that both drives cell movement towards cAMP and couples to a global inhibitory signal that suppresses pseudopod in the back of the cell – a local excitation global inhibition

Fig. 4 Gene regulation by cell–cell signaling during *Dictyostelium discoideum* development. Starvation and the quorum sensing factors CMF and PSF trigger expression of early development genes and low levels of aggregation genes. cAMP pulses further upregulate aggregation genes. Once aggregated higher cAMP levels induce prespore gene expression and DIF production. DIF in turn induces expression of some prestalk genes. Ammonia, which accumulates through protein degradation, prevents terminal stalk and spore maturation in migrating slugs. Rising culminants lose ammonia by gaseous diffusion, stalk cells mature and produce a peptide, SDF, which triggers spore maturation. High osmolality and discadenine prevent spore germination in the spore head, but, once dispersed, spores germinate when exposed to food. Reproduced from Scott, C., Schaap, P., 2009. *Dictyostelium*. In: Schaechter, M. (Ed.), *Encyclopedia of Microbiology*. Oxford: Elsevier, pp. 606–616.

Fig. 5 The network for production of cAMP pulses. Pulsatile cAMP secretion results from positive and negative feedback loops acting on cAMP production. Amoebas first secrete a little cAMP, which binds to the cAMP receptor cAR1 to activate the adenylyl cyclase ACA in an indirect manner that involves phosphorylation of the membrane phospholipid PIP2 to form PIP3. Adenylyl cyclase activation terminates because cAMP also causes desensitization of cAR1, which blocks further cAMP accumulation. Hydrolysis of extracellular cAMP by the cAMP PdsA resets the system for the next pulse. Reproduced from Scott, C., Schaap, P., 2009. Dictyostelium. In: Schaechter, M. (Ed.), Encyclopedia of Microbiology. Oxford: Elsevier, pp. 606–616.

Fig. 6 How do cells detect a cAMP gradient and move forward? (a) Amoebae move up a cAMP gradient by extending a pseudopod in the direction of the highest cAMP concentration and then pulling in their rear end. Pseudopod extension requires polymerization of the major cytoskeletal protein actin at the front of the cell, and is associated with a cAMP increase of the membrane phospholipid PIP₃. PIP₃ is formed via ras activation of PI3 kinase, which phosphorylates PIP₂. (b) PI3 kinase activity increases PIP₃ in the F-Actin leading edge of the cell, whereas the phosphatase PTEN degrades PIP₃ in the rear of the cell. Reproduced from Scott, C., Schaap, P., 2009. Dictyostelium. In: Schaechter, M. (Ed.), Encyclopedia of Microbiology. Oxford: Elsevier, pp. 606–616.

(LEGI) mechanism. However, the mechanisms initiating cell orientation towards the cAMP source and maintaining the “memory” of that direction as the cAMP pulse passes the cell remain to be established, but may involve the protein kinase, ERK1, and the protein complex assemble around Scar, also known as WAVE.

Multicellular Development

After cells have formed the mound (Fig. 4), cAMP pulses continue to be emitted by the aggregation centre. The source of the pulses now moves to the top of the aggregate. The cells on top of the mound start to secrete cellulose and matrix proteins, which form a sheath around the structure that eventually extends over the entire aggregate. The cells continue to chemotax toward cAMP pulses emitted by the tip, but due to the pressure imposed by the sheath are forced to move upward, forming a finger-shaped slug that due to gravity eventually falls over. At this point the slug begins to migrate toward warmth and light, which in nature would be the soil

surface. These so-called thermotactic and phototactic responses are important, since localization of the fruiting body at the soil surface facilitates the dispersal of the spores.

While the mound forms, cells begin to differentiate into prespore and prestalk cells, the precursors of the spore and stalk cells that form during culmination. They are initially randomly distributed, but sort so that a group of the prestalk cells, the pstA cells, are present in the front 20% of the slug, and the prespore cells are in the rear 80%. This rear portion also contains other group of prestalk cells, the so-called anterior-like cells (ALC). Progression through the developmental program is due to regulated expression of genes at different stages, controlled by cell–cell communication. cAMP pulses continue after aggregation, but ACA is lost from most cells in the rear of the slug. These cells start to express a different adenylyl cyclase, ACG, which produces a constant output of cAMP that soon reaches micromolar concentrations. This is the signal that triggers the expression of prespore genes.

Prespore cells also secrete a dichlorinated alkyl phenone, known as DIF. This low molecular weight molecule inhibits prespore differentiation. DIF addition to isolated cells induces both prestalk cells and formation of stalk cells. The DIF biosynthesis genes have been identified and DIF-less mutants created. Remarkably, when developed these mutants still form pstA cells and a stalk. However, they lack the ALC cells that eventually form the upper cup cells during culmination. In contrast to the pstA cells, a second population of prestalk cells, the pstB form the basal disc, but are suppressed by cAMP. Loss of the *Dictyostelium* orthologue of GSK-3, a regulator of developmental cell fate in animal cells, de-represses the effect of cAMP on pstB cells and changes the proportions of basal disc cells to spores in the fruiting body. During later stages of *Dictyostelium* development GSK-3 is also required to prevent premature expression of stalk genes during culmination. This leaves the question of what controls the formation of pstA and stalk cells. This is not fully understood but a series of transcription factors, have been shown to control pstA cell formation. These include the STAT orthologues, DstA and DstC, the bZip proteins, DimA and DimB, and an myb family gene, MybE. Interestingly, the conversion of pstA cell to stalk cells requires dicyclic-GMP, a signal molecule normally only found in bacteria.

Culmination

At the onset of fruiting body formation, culmination, the slug points its tip upward and the prestalk cells start to construct a cellulose tube. This occurs within the tip region, with cells joining the stalk tube at its top, where they differentiate into stalk cells. This process involves the construction of a cellulose cell wall, the formation of a central vacuole, and uptake of water to provide rigidity, and ultimately cell death. The outer surface of the stalk tube is laid down by a collar of cells, held together by adherens junctions in a similar configuration to the polarized epithelia of animals. The prespore cells are raised up the growing stalk, where they mature into spores. The process of spore maturation involves fusion of prespore vesicles with the plasma membrane forming the first layer of the three-layered spore coat. The ALCs move both up and down through the spore mass to form the ancillary supporting structures of basal disc and upper and lower cups.

Ammonia (NH_3) is an important regulator of culmination. During aggregation and particularly in the prestalk cell population during multicellular development, cells degrade their own proteins for energy and metabolites. This causes production of large amounts of ammonia, which has several roles. First, ammonia suppresses the prestalk and prespore cells from maturing into stalk cells and spores. Second, it prevents the ALCs from moving into the prestalk region. If prestalk cells in the tip are lost during migration and no longer produce ammonia, the inhibitory effect is relieved and the ALCs move to the front of the slug to take the place of the lost prestalk cells. All this changes during culmination. Incident light causes the slug to point its tip upward and initiate the culmination process. The tip is now exposed to air and loses ammonia by gaseous diffusion. The loss of ammonia allows the prestalk cells to mature into stalk cells. Ammonia binds to the sensor domain of a histidine kinase, DhkC, to activate RegA via its response regulator domain. RegA contains a phosphodiesterase catalytic domain, and suppresses cAMP-dependent protein kinase (PKA) activity by lowering intracellular cAMP levels. So when ammonia is lost during culmination, RegA loses its phosphoryl group and becomes inactive, allowing PKA activation.

PKA is an important intracellular regulator in eukaryotes. Its cAMP binding domain is also conserved in prokaryotes, where it is part of the catabolite repressor protein, a cAMP-activated transcription factor. *Dictyostelium* PKAs consist of a single catalytic subunit (PKA-C) and a single regulatory subunit (PKA-R). Metazoan PKAs have two of each. PKA is activated when cAMP binds to the regulatory subunit, which then dissociates from the catalytic subunit, thus activating the enzyme. PKA-C and PKA-R levels are low in growing cells and PKA activity is not required for growth. PKA-C is translationally upregulated at the onset of starvation in a process that is most likely activated by the quorum sensor, PSF. This up-regulation is essential for initiation of development, and PKA activity is required for cAMP secretion during aggregation. However high levels of PKA activity are required for both spore cell and stalk maturation.

Three adenylyl cyclases are active during development, ACA during aggregation, ACB in stalk cells and ACG in prespore and spore cells. They all generate the cAMP to activate PKA. However, during culmination it is cAMP degradation by RegA that holds the balance for PKA activation. In addition to ammonia acting via DhkC, the peptide SDF controls RegA via a second histidine kinase DhkA. This peptide is generated by cleavage of the protein AcbA, secreted by prespore cells and cleaved by a protease TagC present on the surface of prestalk cells. In contrast to DhkC, SDF de-activates DhkA causing a reversal of its associated phosphorelay pathway to remove the phosphoryl group from RegA, an increase of cAMP and PKA activation in prespore cells to cause their maturation into spores. Together, ammonia and SDF make sure that stalk cells and spores are formed at the right time and position in the fruiting body (Fig. 7).

It is remarkable that many of the signals that control *Dictyostelium* development, such as ammonia, high osmolarity, and discadenine, do so by regulating the activation status of PKA. In *Dictyostelium*, PKA plays a central role in timing and coordination of

Fig. 7 External signals regulate spore and stalk maturation by altering intracellular cAMP levels. Terminal spore and stalk maturation require high levels of cAMP-dependent protein kinase (PKA) activation by accumulation of intracellular cAMP. In prestalk cells cAMP is produced by ACB and in prespore cells by ACG. The cAMP phosphodiesterase RegA degrades intracellular cAMP but requires phosphorylation to be active. The phosphoryl group is provided by a sensor histidine kinase that can act as either a kinase or a phosphatase when a ligand binds to the sensor domain. The kinase autophosphorylates a histidine residue and via a series of histidine to aspartate to histidine transfers the phosphoryl group is carried over to RegA. Ammonia activates the histidine kinase activity of DhkC, thereby causing activation of RegA and preventing cAMP accumulation. Reproduced from Scott, C., Schaap, P., 2009. Dictyostelium. In: Schaechter, M. (Ed.), Encyclopedia of Microbiology. Oxford: Elsevier, pp. 606–616.

development. It does not stop there, because although stalk cells die in the fruiting body, spore cells remain viable for long periods until dispersal. It is vitally important that spores only germinate when they are dispersed and the emerging amoebas are surrounded by food. Two factors, ammonium phosphate and a modified adenine called discadenine, are present in the spore head to prevent spore germination *in situ*. Ammonium phosphate acts by raising the osmolality in the spore head to high levels. Again this involves a PKA mediated process, as high osmolality activates the osmosensor of the adenylyl cyclase ACG, causing intracellular cAMP production and PKA activity that inhibits spore germination.

Conclusions

The Dictyostelid social amoebas have fascinated biologists for almost 150 years by their alternation between a single state during growth, and multicellular development into fruiting bodies. Combined with their ease of culture and excellent experimental and genetic tractability this versatility makes them an outstanding tool to resolve a broad range of questions in molecular, cellular, and developmental biology. With the discovery that many human disease genes are conserved in Dictyostelids, investigation of the molecular basis of human afflictions has recently been added to this repertoire.

This article provides a generalized overview of current knowledge of the biology of the Dictyostelids, summarizing studies of many of our colleagues. More detailed information about their work can be found in the Further Reading section.

Glossary

Antioxidant enzymes SOD (superoxide dismutase) Metalloenzyme that degrades superoxide radicals into hydrogen peroxide and molecular oxygen.

Basic nuclear proteins DNA-binding proteins of low molecular weight present in the chromatin of dinoflagellates.

Dikaryon Cell with two nuclei.

Dinoflagellates (phylum Dinoflagellata) A group of unicellular eukaryotes that are essentially biflagellated and possess a dinokaryon.

Dinokaryon The nucleus of dinoflagellates, characterized by the presence of a permanent nuclear envelope and chromosomes in a quasi permanently compacted state.

Dinomitosis Mitosis of the dinokaryon characterized by the presence of an extranuclear mitotic spindle crossing the nucleus *via* cytoplasmic channels.

Ecdysis Act of molting or shedding of the theca.

Endosymbiosis The condition of one organism living inside the cells of a different species where neither organism is harmed.

Nucleosomes Protein complexes consisting of histone protein octamers, which are present in most eukaryotic chromatin except that of dinoflagellates.

Ocellus The most complex algal eyespot, present only in several dinoflagellate species.

Pelagic Describing or referring to animals living in the marine domain, either swimming or passive; opposite to benthic (living on the bottom).

Peridinin A carotenoid pigment specific to most autotrophic dinoflagellate.

Theca Total cell wall, consisting of cellulose plates in dinoflagellates.

Abbreviations

FeSODs Iron SODs

SOD Superoxide dismutase

Defining Statement

The diversity of dinoflagellate morphology and lifestyles is presented with emphasis on model organisms. These include heterotrophic (*Cryptocodinium cohnii*, *Noctiluca scintillans*), autotrophic (*Prorocentrum micans*), mixotrophic (*Blastodinium* sp.), and parasitic (*Syndinium* sp.) species. Cellular and molecular analyses including some puzzling questions regarding dinomitosis, evolution, cell architecture, eyespots and an antioxidant enzyme are discussed.

Introduction

With their large distribution throughout all the seas and freshwater bodies of the world, dinoflagellates play a prominent role in the trophic chain and in water ecology. They constitute a major group of unicellular eukaryotic microbes and can be autotrophic (about half are photosynthetic), heterotrophic, parasitic and/or mixotrophic, or symbiotic. Current classification recognizes approximately 161 genera, 48 families, and 17 orders or a total of ~6000 described species. Cells are typically biflagellated and generally the two flagella are oriented perpendicular to one another. This results in a characteristic spiral locomotion from which the group derives its name (*dino*, in Greek means 'to turn'). Most autotrophic dinoflagellates possess a characteristic carotenoid pigment, peridinin, in association with chlorophylls *a* and *c* and other pigments such as β -carotene, diadinoxanthin, and dinoxanthin.

[☆]*Change History:* October 2018. Marie-Odile Soyer-Gobillard updated the text (souligned in yellow) and add three figures (Figs. 11, 17, and 21). Fig. 11: From Soyer-Gobillard, M.-O., et al., 2002. By copyright permission from Vie Milieu Life and Environment. Fig. 17: Reproduction of a draw from an original plate (Pl. XIV) of the doctoral Chatton's thesis (1920) Archives de Zoologie Expérimentale et Générale 1920, 59, 1–475. Journal not yet published. Chatton del. Fig. 21: From Moon, E., et al., 2015. With permission of Elsevier.

This article is an update of M.-O. Soyer-Gobillard, Dinoflagellates, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009.

One of the most striking features of dinoflagellates is their nucleus (dinokaryon). Although the pattern of dinoflagellate DNA synthesis is typically eukaryotic, they are the only eukaryotes in which the chromatin is totally devoid of histones and nucleosomes. Instead, it contains specific DNA-binding basic proteins. The only known exception to this is the plasmodial genus *Syndinium* in which basic nuclear proteins (histone-like) have been detected using alkaline fast green staining.

Dinoflagellate diversity has inspired not only numerous scientific studies but also artistic representations. These include the wonderful drawings of Ernest Haeckel (1834–1919) and Edouard Chatton. For example, Fig. 1 shows a drawing of several free-living dinoflagellate of the genus *Pyrocystis*, which is still actively studied for its bioluminescent properties (see “Relevant Website section”).

Dinoflagellate Evolution

The great protistologist and cell biologist Edouard Chatton (1883–1947) was the first to distinguish between prokaryotic and eukaryotic microbes and to propose a tentative protist classification. However, it was Haeckel who coined the term ‘protist’ in the nineteenth century, although he also included bacteria in that group. Dinoflagellates are now recognized as one of the major division of the eukaryotic supergroup Alveolata, which is further included in the supergroup Chromalveolata. Like other members of the chromalveolates, phototrophic dinoflagellates have acquired their plastids by secondary endosymbiosis. This appears to have occurred multiple times during dinoflagellate evolution and at least two cases of tertiary endosymbiosis have now been documented in this group.

The first and undisputable fossil dinoflagellate cyst is from the Triassic (c.200 million years ago). However, biogeochemical evidence suggests the presence of dinoflagellate ancestors as far back as the Early Cambrian. This is based on the discovery of triaromatic dinosteroid, sedimentary biomarkers characteristic of dinoflagellates. This suggests that these protists are much older than their fossils suggest. The major diversification of modern dinoflagellates occurred during the Jurassic radiation based on the presence of numerous cysts and thecal plates, which were first formed by photosynthetic dinoflagellates. However, these dates based on morphological and cell biology data are not yet fully supported by all the molecular phylogenetic analyses.

Dinoflagellate Diversity

Three species of free-living dinoflagellates and two mixotrophic species belonging to the genera *Blastodinium* and *Syndinium* have been extensively studied as model organisms, and much of what is known about dinoflagellate cell structure is based on this work. These organisms are the heterotrophic species *Cryptocodinium cohnii* and *Noctiluca scintillans*, the photosynthetic species *Prorocentrum micans*, and the mixotrophic species of the genera *Blastodinium* and *Syndinium*.

Cryptocodinium cohnii Biecheler

C. cohnii Biecheler is a marine dinoflagellate whose vegetative cells are devoid of plastids but rich in starch. Two orthogonally disposed flagella are present (Fig. 2), and these disappear just before cell division (dinomitosis), which precedes a complex reproductive cycle. Since 1887, two forms of *C. cohnii* swimming cells and cysts that lack flagella have been recognized. Detailed *in vivo* studies published in the 1990s described the complex cell cycle of this dinoflagellate, which lasts 26 h and results in four daughter cells (Fig. 3). The organism has been used as a model system to study the cytoskeleton and its role in mitosis, the superoxide dismutase (SOD) evolution.

The cytoskeleton of *C. cohnii* has been intensively studied in our lab, particularly the role of F- and G-actin (see further article) and β -tubulin in the maintenance of cell shape (Fig. 4) and their importance in dinomitosis. It was also shown in this species that cortical microtubules do not depolymerize during mitosis, and now this has also been shown in the species *Oxyrrhis marina*. Microtubules of cytoskeleton are accompanied by heat shock protein P72. This may play a protective role for the cortical microtubules, for example, by preventing microtubule depolymerization during mitosis. This well-conserved protein could also play an important role in the regulation of microtubule formation.

SODs, which catalyze the degradation of toxic superoxide radicals, have been studied only recently in dinoflagellates. A multicopy gene family (about 20 genes) encoding iron SODs (FeSODs) was discovered and characterized in a heterotrophic dinoflagellate, while MnSOD and FeSOD activities were detected in *Symbiodinium* sp., a dinoflagellate living in symbiosis with the sea anemone *Anemonia viridis*, and FeSOD, MnSOD, Cu/ZnSOD were found in the photosynthetic dinoflagellate *Lingulodinium polyedrum* (formerly *Gonyaulax polyedra*). In another photosynthetic dinoflagellate, *Karenia brevis*, both MnSOD and FeSOD have been identified but only by Western blotting. It is thought that these enzymes might play an important role in the survival strategy of this Florida red tide microorganism. Enzymatic assays of SOD activity indicate the presence of two different FeSOD activities in *C. cohnii* lysates, whereas MnSOD and Cu/ZnSOD were not detected in this species. This contrasts with the situation previously characterized in other photosynthetic dinoflagellates.

Phylogenetic analyses including 110 other dimeric FeSODs from a wide range of bacteria and eukaryotes showed that the *C. cohnii* SODs form a monophyletic group (Fig. 5). These results (2008) suggest that all dinoflagellates primitively had a cytosolic FeSOD of bacterial origin, while the MnSOD of mitochondrial ancestry was lost and replaced by a second copy of FeSOD.

Fig. 1 Several free-living bioluminescent dinoflagellates of the genus *Pyrocystis* Murray ex Haeckel, 1890. The species *Pyrocystis pseudonociluca* is shown in the second row at the right-hand side; *Pyrocystis lunula* in the third row at the right-hand side. Eyespot

The ocellus of dinoflagellates, an unusual photosensitive organelle, is the most complex algal eyespot known. It is present in several heterotrophic dinoflagellates such as *Nematodinium*, *Warnowia*, *Erythropsis* and several Woloszynskioids. Eyespot is considered as an important phylogenetic marker in dinoflagellates. More often located toward the posterior end of the cell, the most sophisticated structure measures about 25 μ m long by 15 μ m wide. It is composed of a pigment cup, retinoid, and lens and it functions as a photoreceptor. As suggested by W. J. Gehring in 2004, this photosensitivity probably arose first in cyanobacteria, and was later acquired by the first photosynthetic eukaryotes (archaeplastida) via the cyanobacterial endosymbiosis that gave rise to the plastid. Dinoflagellates would then have acquired this photosensitivity from a red alga via secondary chloroplasts. In some dinoflagellate species this plastid evolved into an elaborate and sophisticated photoreceptor organelle, which is found in some dinoflagellate species that lack chloroplasts, such as those cited above. Because some dinoflagellates such as zooxanthellae are commonly found as symbionts in cnidarians, for example, these organisms could then have transferred their photoreceptor to cnidarians.

Fig. 5 Neighbor-joining tree based on protein sequences of dimeric FeSODs and closely related SODs. Accession numbers or references of the sequences retrieved from genome sequencing projects are given in Dufernez, F., Yernaux, C., Gerbod, D., et al., 2006. The presence of four iron containing superoxide dismutase isozymes in Trypanosomatidae: Characterization, subcellular localization, and phylogenetic origin in *Trypanosoma brucei*. Free Radical Biological Medicine 40, 210–225. The full-length *Cryptosporidium cohnii* SOD1 sequence obtained in this study is boxed, whereas the chloroplast sequence from *Lingulodinium (Gonyaulax) polyedrum* is indicated by an arrow. If experimentally determined, the subcellular localization of protist SODs is indicated in parentheses. The scale bar corresponds to 0.1 substitution (corrected) per site. ***Noctiluca scintillans* McCartney**

N. scintillans McCartney is a model for studying the complex heterotrophy found in some dinoflagellates. Cytoskeletal elements that participate in the motility of the *N. scintillans* trophozoite are also involved in related nutritional functions. These elements are located at the level of the tentacle (Fig. 6) and of the cytostome where filaments are found organized into myonemes and cytoplasmic fibrils organized into striated and contractile strip. As shown in Fig. 8, microtubules are located just under the peripheral ectosarc, which is responsible for calcium exchange by means of epiplasmic channels, and are oriented parallel to the major axis of the tentacle. In the schematic drawing of transverse section (Fig. 7), the convex part is equipped with a large number of microtubule rows that are crosslinked with each other (Fig. 8, arrows). Striated myonemes are distributed along the tentacle or linked to one another by a knot (Fig. 7). The tentacle also contains numerous mitochondria. This complex system together with extracellular calcium ions sequestered in mitochondria is responsible for this dinoflagellate's motility and feeding. Tentacle contraction involves ectosarc deformation, myonem contractility, and microtubule modifications. The major contractile protein of this system that plays an important role in determining cell shape is the epiplasmic actin protein, P45. Cytochemical investigations about the presence of histone-like proteins in the trophocyte nucleus, using in particular alkaline fast green, were negative. At the molecular level, the unusual nucleotide containing the base 5-hydroxymethyluracil has been found in the nuclear DNA of *N. scintillans*. In the up to now investigated dinoflagellate species this unusual base replaces 12%–68% of the thymines that constitutes a relatively important level of replacement amount.

Fig. 6 *Noctiluca scintillans* McCartney. (a) and (b) Interference phase-contrast views. (a) Trophozoite with its tentacle (T) seen relaxed and (b) contracted. Tracts of myonemes (arrows) are anchored between the cytostome (Cy) and the supporting rod (SR). Scale bar = 200 μm . (Photos J. Lecomte). Magnification $\times 200$. Prorocentrum micans Ehrenberg

P. micans is a model for autotrophic dinoflagellates. In this species, the pellicle covering the whole surface of the theca (the epitheca) is a kind of polysaccharidic ‘skin’. This fragile structure surrounding the entire cell was observed only under SEM with careful preservation (Fig. 9). The cell cycle of *P. micans* is typically eukaryotic despite the unusual structure of the dinoflagellate chromatin when compared with that of most eukaryotes. The population doubles every 6 days and the S phase of DNA synthesis lasts 4 h. From the end of replication to the end of mitosis (G2 + M phases), the time taken on average is 8 h. Phases S + G2 + M take less than 12 h and the G1 phase lasts 120 h (Fig. 10). This is despite the fact that *P. micans* has more than 100 chromosomes of 1 μm in diameter and a large DNA content of 42 pg cell^{−1}.

In *P. micans*, vegetative cells are haploid and reproduce by binary division. Sexuality can be experimentally induced by changing the culture medium (switching from Erd Schreiber’s to Provasoli’s medium) or by subjecting cultures of this photosynthetic species to unfavorable conditions such as darkness and low temperature (4°C).

Mating in dinoflagellates occurs by conjugation (Figs. 11 and 12). This begins with the formation of a conjugation tube between the two conjugants, followed by passage of one nucleus *via* the tube. Then, this tube enlarges and the sexual cells fuse, leading to the formation of a dikaryon (cell with two nuclei). There is commonly an absence of fundamental morphological differences between vegetative cells and gametes. The only visible differences are a small variation in pigmentation and cell size. Many different sexual processes occur in dinoflagellates (Table 1), but *P. micans* is unique in having a fertilization tube that permits the transfer of all genetic material (male gametic nucleus) and in the formation of a partition between the empty sexual cells and the dinokaryon. Dinoflagellates appear to be highly specific in terms of environmental factors that induce sexuality. This is probably related to the extreme diversity in their life cycles and way of life.

Mixotrophic Dinoflagellates

Mixotrophic (parasitic) Dinoflagellates were first described by Chatton in his magisterial doctorate thesis, published in 1920. He was particularly interested in *Blastodinids*, which he first discovered in the digestive tract of pelagic copepods. As shown in Figs. 13 and 14, *Blastodinids* are binucleated cells. Two kinds of cells are present: the trophocyte, which remains temporarily undivided while it increases in size; and the gonocyte, which produces sporocytes in which the chromatin is progressively more and more

Fig. 9 (a) *Prorocentrum micans* autotrophic cell apical view observed with scanning electron microscope. Observe the peripheral polysaccaridic 'skin'.

Two longitudinal flagella of this predividing cell run more or less parallel to each other. One undulating flagellum arises from the same opening of the epitheca as the longitudinal ones, but adheres to its outer layer; anchoring threads strengthen this adhesion, and bridging threads connect every second wave of the undulating membrane. On the epitheca also lie adsorbed extruded fibrous trichocysts and undefined filaments, probably of bacterial origin. (b) Terminal portion of the undulating flagellum. There are no anchoring or bridging threads on its free tip. Magnification $\times 11,500$. a.t., anchoring thread; b.t., bridging thread; fl1, fl2, longitudinal flagella; f.t., free tip; tr. trichocyst; u.fl., undulating flagellum; u.mb., undulating membrane. Journal no longer published.

condensed after successive divisions. Layers of sporocytes lead to the formation of biflagellate swarming dinospores, which are later released in seawater. Trophocytes can also divide longitudinally and produce other parasites into the same digestive tract. In Fig. 14, the two nuclei are seen clotted in anaphase with 'plasmodendrites' (cytoplasm) passing through the nuclei. In 1971, Soyer (Gobillard) showed with transmission electron microscopy that the *Blastodinium* mitotic spindle is located in these channels and linked to the spindle poles, which lack centrioles. During mitosis, the chromosomes of the sporocytes become increasingly compacted and are attached to the nuclear envelope. The latter has differentiated cytoplasmic channels that allow the microtubules of the mitotic spindle to pass through the nuclear membrane (Fig. 15).

Chatton also described the genus *Syndinium*, whose various species parasitize marine copepods or various radiolarians. On the basis of the morphology of the spores released by their free-living swimmers, Chatton considered *Syndinium* a ‘specialized’ dinoflagellate. This was also due to the apparent simplicity of *Syndinium* cell division, and the fact that the species had only five chromosomes (Fig. 16). On this basis, Chatton proposed it as a model for dinoflagellate mitosis, specifically referring to it as ‘syndinian mitosis’ (Fig. 17).

Later, ultrastructural studies showed this to be very particular peridinian mitosis. The mechanism consists of a permanent closed nuclear membrane outside of which lies an extranuclear mitotic spindle with centrioles and kinetochores that attach to the inner surface of the nuclear membrane (Figs. 18 and 19). This is in contrast to most other dinoflagellates, which have neither centriole nor kinetochore. Moreover, most typical dinoflagellate chromosomes lack basic proteins such as histones, but instead have specific basic nuclear protein associated with their DNA. Two exceptions to this are *Syndinium* sp. and the symbiotic zooxantellae, which have appreciable amounts of basic proteins of the histone family associated with their DNA. Further biochemical and molecular studies are needed to analyze more thoroughly and to characterize these basic nuclear proteins.

Detailed description of a new planctonic free living mixotrophic Dinoflagellate, *Paragymnodinium shiwhaense*, was published: its morphology, pigments and ribosomal DNA gene sequence analysis suggested that it is a new species into a new genus. The distinctive feature of this species is the presence of both chloroplasts and nematocysts, organelles used for the prey capture as also present in the polynucleated *Polykrikos* dinoflagellate, in addition to fibrous trichocysts, which are detoxication organelles. In addition to the photosynthesis, *P. shiwhaense* sucks the preys through its peduncle. Several photosynthetic species of Dinophyceae as *Dinophysis acuminata* or *D. norvegica* were the first (1994) to be described as mixotrophic with the presence of food vacuoles into the cell. They are predators for other dinoflagellates or other unicellular planctonic organisms and can have an important grazing impact on algal populations.

Evolution of the Mitotic Apparatus

Most dinoflagellates have a closed mitosis in which the nucleus is surrounded by a persistent nuclear envelope. Within this nucleus the chromosomes are maintained in a quasipermanently compacted state. Chromosome separation is accomplished by an extranuclear microtubular mitotic spindle located in cytoplasmic channels that pass through the nuclear membrane during mitosis.

Two centrosome regions without centriole are linked to the kinetosomes by two microtubular structures called ‘desmoses’ as shown on the diagrammatic representation of a dinoflagellate in Fig. 20: in this diagram, is represented the mitotic apparatus schematized in anaphase with listed and framed the up-to-now detected associated proteins. Exceptions among these species-models include rare species such as the coelomic parasite *Syndinium* sp. (see below), *Oxyrrhis marina* and *N. scintillans*, which show considerable variations when compared with the well-known *C. cohnii* model of mitosis.

Syndinium and related species that parasitize invertebrates were classified as dinoflagellates by Chatton and others on the basis of the morphology of their zoospores. However, the biochemistry of their chromosomes (presence of specific basic proteins) and electron microscopic observations demonstrated fundamental differences in their mitotic apparatus as compared with the rest of the dinoflagellates. In *Syndinium* and relatives, the four V-shaped chromosomes are permanently attached at their apex to a specific area of the nuclear membrane through a kinetochore-like trilaminar disk inserted into an opening in the membrane (Fig. 19). Microtubules connect the dense layer of each kinetochore to the base of the two centrioles located in an invagination of the nuclear envelope (Fig. 18). In these species, centrioles or basal bodies are intimately involved in chromosome segregation. This is not the case in *Cryptocodinium*, where the basal bodies are indirectly involved with the microtubular spindle, or in *Blastodinium*, where the nuclear envelope functions as the motor for chromosome segregation.

As soon as 1996, for the first time, by means of monoclonal and polyclonal anti-actin antibodies, Soyer-Gobillard et al. were able to demonstrate the presence of F- and/or G-actin in two species of dinoflagellates *Prorocentrum micans* and *Cryptocodinium cohnii*, either by biochemistry, immunofluorescence and in TEM. SDS-PAGE electrophoresis and immunoblotings made either from total or nuclear protein extracts revealed the presence of a 44-kDa band reacting with monoclonal anti-actin antibody in two species, and thus demonstrated the presence of actin in nuclear and cytoplasmic fractions. After squash preparation of *P. micans* cells, actin was identified within the nucleus and in some regions of the cytoplasm by immunofluorescence microscopy. Labelling of both nucleolus and centrosome region was evident together with amorphous nucleoplasmic material surrounding the chromosomes. The use of cryosections of intact *P. micans* and *C. cohnii* cells for immunofluorescence along with staining with DAPI to delineate the chromosomes themselves, yielded finer resolution of the intranuclear network labelling pattern. In *P. micans*, in addition to the centrosome region, the cytoplasmic channels passing through the nucleus in dividing cells are labelled. In *C. cohnii*, the cortex, the centrosome region, the cytoplasmic channels, the region surrounding the nucleus, the filaments linking it to the cortex and the cleavage furrow are also labelled. In the nucleus of the two species, there is a prominent ‘weft’ of fine actin filaments in the nucleoplasm forming a matrix of varying density around the persistent chromosomes. This actin matrix, of unknown function, is most conspicuous at the end of the S-phase of the cell cycle. Fluorescent derivatives of phalloidin, used as diagnostic cytochemical probes for polymeric actin (P-actin), gave similar results. Positive TEM immunolabelling of intranuclear actin confirms its presence in the nucleoplasm and in the nucleolus where the preribosomal region is labelled. In the cytoplasm, lips of the cleavage furrow and kinetosome regions are labelled as well as the centrosome region. The possible functions of this protein located in several compartments of dinoflagellate cells were recently lightened and all these observations confirmed by Berdieva et al. (2018), in another *Prorocentrum*, *Prorocentrum minimum* (Pavillard) Schiller 1933: *Prorocentrum minimum* is an armoured, marine, planktonic, bloom-forming dinoflagellate. It is a toxic cosmopolitan species common in cold temperate brackish waters to tropical regions. In this species, actin is also involved in fundamental nuclear processes and participates in cell shape determination, cell cover rearrangement and development during ecdysis.

Fig. 11 Course of pairing (A)–(C), mating (D)–(F) and beginning of sexual reproduction (G)–(K) of *Prorocentrum micans* as observed *in vivo* after staining of the nuclei with DAPI and fluorescence coupled with Nomarski interference light microscope observations. During pairing and conjugation, several cell pairs presented a bright (red) autofluorescence (A), (C), (E), (G), (H). (A)–(C). During pairing the cells are disposed with the anterior part of one cell in front of the other anterior part, apical spine against apical spine. The two nuclei are distally disposed. (D) Note the fixation of one of the apical spines anchored into the partner cell (arrow) at the beginning of mating. (E)–(G) After the formation of a fertilization canal, and injection of one nucleus of the donor cell into the receiver (F), the two nuclei are located in the same cell (G). H, After conjugation of the nuclei, replication occurs. The nucleus containing 4q DNA presents very thin and punctuated chromosomes (arrow). An intense rotation movement (cyclosis) is also observable in the nucleus. The outline of the nucleus is wavy and three nucleoli (nu) are visible. (I)–(K) The first nuclear meiotic division takes place but cytoplasmic segregation does not occur. Meiosis is incomplete. Reproduced from Bhaud, Y., Soyer-Gobillard, M.O., Salmon, J.M., 1988. Transmission of gametic nuclei through a fertilization tube during mating in a primitive dinoflagellate, *Prorocentrum micans* Ehr. *Journal of Cell Science* 89, 197–206. Fig. 12 (A)–(I) Diagram of the partial course of sexual reproduction phases of the dinoflagellate *Prorocentrum micans* from *in vivo* and TEM observations of the nuclei after exposure of the cultured cells to low temperature (4°C) and darkness. Vegetative cells functioning as isogametes (A) and containing *q* DNA become paired by means of their respective apical spines (B), then the donor cell injects its nucleus with stretched chromosomes into the receiver cell (C). After the two nuclei conjugate (D) in the zygote containing *2q* DNA (E), crossing over of the chromosomes occurs. Chromosomes become completely unwound, stretched, and replicated. In the nucleus containing therefore *4q* DNA (F), chromatin begins to spin round (chromatic cyclose) giving a round shape to the nucleus as shown in the photograph (F'). Only one meiotic division occurred (G, G', H), leading to an incomplete separation of the *2q* DNA-containing cells (I). Reproduced from Bhaud, Y., Soyer-Gobillard, M.O., Salmon, J.M., 1988. Transmission of gametic nuclei through a fertilization tube during mating in a primitive dinoflagellate, *Prorocentrum micans* Ehr. Journal of Cell Science 89, 197–206. (f) Early daughter nucleus with persisting channel and microtubules. Reproduced from Ris, H., Kubai, D.F., 1974. An unusual mitotic mechanism in the parasitic protozoan *Syndinium* sp. *Journal of Cell Biology* 60, 702–720. By copyright permission from The Rockefeller University Press.

Fig. 20 Diagrammatic representation of a dinoflagellate (except *Syndinium*) mitotic apparatus schematized in anaphase with listed and framed the up-to-now detected associated proteins. Microtubular mitotic spindles lie throughout the nucleus, pass into the archoplasmic spheres, and are linked to the two pairs of kinetosomes. AS, archoplasmic sphere (containing Golgi bodies); C, centrosome (without any centriole); ECC, extranuclear cytoplasmic channel; MMS, microtubular mitotic spindle; MD, microtubular desmose; Kt, kinetosomes; N, nucleus; NE, nuclear envelope (permanent); Ch, chromosomes. Reproduced from Ausseil, J., Soyer-Gobillard, M.O., Géraud, M.L., 2000. Dinoflagellate centrosome: Associated proteins old and new. *European Journal of Protistology* 36, 1–19. By copyright permission from Elsevier publisher.

Conclusions

The first evidence of dinoflagellates in the fossil record is the biogeochemical analyses of early Cambrian sediments (c.520 million years ago), which detect the presence of dinoflagellate-specific dinosterols. Despite the great diversity of dinoflagellates in terms of their physiology, lifestyle, and cell cycle, they are remarkably similar in their mitosis except for *Syndinium* spp. and *Oxyrrhis marina*. The system of cytoplasmic channels passing through the intact nucleus indicates that microtubules are never in direct contact with the chromosomes but are always separated from them by the persistent nuclear envelope. Despite the absence of histones and nucleosomes in the chromatin of some species, dinoflagellates still have a typical eukaryotic cell cycle. According to [Marinov and Lynch \(2016\)](#), which have applied large-scale mRNA sequencing to 11 species of dinoflagellates, including strains of the syndinean genera *Hematodinium* and *Amoebophrya*, parasites of crustaceans and dinoflagellates, respectively, to optimize and update the dinoflagellate tree, we now know that dinoflagellates belong to the alveolates, together with apicomplexans and ciliates, and that it is highly probable that the loss of nucleosomes is a derived feature. Although an enormous amount of work have yet began about dinoflagellate chromatin, transcription, transcriptional and post-transcriptional regulation as see in [Soyer-Gobillard and Dolan \(2015\)](#), the mystery of dinoflagellate chromatin remains largely unresolved and there is still too little molecular data to sufficiently resolve relationships among the diverse dinoflagellates. Thus, morphological and cell biological analyses will continue to constitute a vital tool for dinoflagellate phylogeny ([Fig. 21](#)).

In addition to their fundamental interest for cell and evolutionary biologists, autotrophic dinoflagellates constitute part of the enormous energy potentially available from the phytoplankton. The heterotrophic *C. cohnii* is also intensively cultivated as a source of maternal milk due to the presence of long chain fatty acids in these organisms. Dinoflagellates are also important as symbionts of corals, where they play important role(s) in the health and survival of their hosts. The impact of toxic dinoflagellates such as species of *Pfisteria*, *Alexandrium*, *Gymnodinium*, *Dinophysis*, *Karenia*, and others on fish and shellfish industries is substantial and possibly is still significantly underestimated. Indeed, toxic incidents resulting from these different dinoflagellate species are being reported frequently throughout the world, particularly near the coasts. This increase of toxic blooms seems linked to the eutrophication of coasts and the spreading of species due to an increase in commercial exchanges. Thus, the importance of these species, which produce some of the most potent neurotoxins known to man, should not be underestimated.

Glossary

Aptamer From the Latin *aptus* meaning “to fit” and the Greek *mer* meaning “repeating unit.” Aptamers are nucleic acid molecules (RNA or DNA) selected to bind to target molecules. The name was born in Jack Szostak’s lab, namely Andy Ellington, who attributes it to friend Nina Tovish.

Chemically modified nucleotide A nucleotide that has been modified chemically to create a new chemical structure that is distinct from standard RNA and DNA nucleotides used by life. For example, 5-benzylaminocarbonyl2′-deoxyuridine or 2′-deoxyuridine modified at its 5-position with a benzyl group.

Directed evolution A synthetic process that harnesses the selection to evolve molecules, typically proteins or nucleic acids, from large, stochastically permuted pools or combinatorial libraries, to have desired properties.

In vitro evolution A general term that refers to a process or method of directed evolution, such as SELEX (Systematic Evolution of Ligands by EXponential amplification), that is carried out in test tubes as opposed to in vivo, or carried out in living systems like cells or organisms.

Selection In directed evolution, a method or process used to select or pick out molecules that have desired properties, such as binding to a target analyte.

SELEX Systematic Evolution of Ligands by EXponential amplification. A process of directed evolution by which molecules are evolved from stochastically permuted pools or combinatorial libraries using exponential amplification, such as polymerase chain reaction (PCR), to have desired properties.

SOMAmer reagents Slow Off-rate Modified Aptamer reagent. A single-stranded nucleic acid molecule that contains chemically modified nucleotides that is selected to have desired properties such as binding to a specific ligand, and has slow dissociation rates.

Evolution and the Central Dogma – DNA, RNA, Proteins

Francis Crick articulated the Central Dogma, and thus directed the next 50 years of research in molecular biology and genetics. While the edges of the Central Dogma have been discussed vigorously, one achieves substantial understanding of biology by keeping the Central Dogma clearly in mind.

The Central Dogma described information flow within the central macromolecules of life – DNA, RNA, and proteins. Single-stranded DNA was easily converted to its complementary strand, and thus DNA could exist as a double-stranded helix or as either single strand without (except for mutations during the replication events) losses or changes in the information encoded by the sequence of nucleotides in DNA. Similarly, transcription (from DNA to RNA) is an accurate process that requires nothing more than accurate reading of DNA by the RNA polymerases to make RNA molecules whose nucleotide sequences reflect the sequences of nucleotides in DNA. The process of translation is also an accurate process, using a complex machine called the ribosome, through which RNA sequences are read, three nucleotides at a time, into the amino acids that comprise a protein. Famously, Crick understood that nucleotide complementarity made all interconversions between DNA and RNA rather simple, while protein sequences could not (in biochemical terms) be read “backward” into nucleic acid sequences. The Central Dogma is discussed fully in the encyclopedia.

The Central Dogma and “Undirected” Evolution

Evolution operates at the level of the Central Dogma, over long time periods. Creatures speciate and evolve (ie, restrict their mating events to others of the same kind) through a slow process related to the multiplication time for that creature (an hour for many bacteria, years for many mammals) and the mutation rate for that creature (ie, the number of nucleotide changes – of any kind – that occurs stochastically to that creature’s genome during each multiplication event). Because of the Central Dogma, changes in the genome (most frequently DNA, although some viruses use RNA, is their genomic substance) lead to changes in RNA sequences and protein sequences. The process of natural evolution occurs over long time periods and is undirected, most of the time. That is, mutations arise in the genomes of creatures and they can be harmful, beneficial, or neutral, but the underlying chemical process (changes in the genome) are almost always random.

[☆]*Change History:* April 2016. L. Gold and J. Walker made minor changes in the text and updated “Further Reading” section.

This article is a reprint of L. Gold, J. Walker, Directed Evolution, *Reference Module in Life Sciences*, Elsevier, 2017.

A classic study of undirected evolution was the extraordinary work on the bacteriophage T4 rII cistrons by Seymour Benzer and by Francis Crick and Sydney Brenner (and, of course, their many colleagues). In many ways, the apogee of modern classic genetics were the studies of the rII cistrons, which led to understanding of the mechanisms of mutagenesis as well as an understanding that the genetic code was read during translation at three nucleotides (a codon) per amino acid.

Breeders of all kinds have tried to enhance the rates of evolution toward desired phenotypes. Tulips, corn, chickens, dogs, cats, race horses, and laboratory strains of mice have been improved through natural evolution; breeders identify a trait of interest and select (historically, by choosing from a group of progeny the ones that seem to have the desired trait) those variants for further mating, and thus screen and isolate natural changes in the genomes of those creatures under study. Because genomes tend to “breed true,” this process has been successful for a long time. (“Breed true” is of course a quantitative term – some creatures, like humans, have low intrinsic mutation rates (perhaps one mutation per generation per 10^9 nucleotides), while viruses often replicate with high error rates (perhaps one mutation per generation per 10^3 nucleotides).) Breeding is thus similar to natural (undirected) evolution, except that it is guided by a predetermined human desire to achieve a particular evolved quality. The essential element of natural undirected evolution is time, largely due to three facts: “breeders” are historically operated from visual clues; the intrinsic mutations rates – at the genomic nucleotide level – are low; and, often, the “growing season” for the creature of interest is brief.

Molecular biologists made possible faster undirected evolution by enhancing the mutation rate at the sites on genomes which were thought to be involved in a process of interest. This work, which was started in the mid-1970s (because DNA synthesis in the lab became widely available), was enabled by the ability to both prepare nucleic acids and replace genes in organisms. With those tools available, scientists were able to “hammer” a region of a genome with heavy mutagenesis to allow a large pool of interesting genomic variants to be screened for a desired trait. In some cases, depending on the creature under study, heavy mutagenesis of a region of a genome was followed by selection of a desired phenotype rather than merely looking for that phenotype. This kind of work was common and was most frequently done in bacteria because gene replacement protocols were powerful for many species of bacteria. The metaphor for such an experiment is simple to imagine: if a bacterial species is unable to grow on some sugar (but is able to grow on many different sugars), one might do heavy mutagenesis of the genes responsible for using sugar #1 as a carbon source and transform the bacteria with copies of the mutated DNA, and then selecting for bacteria that can now grow on the previously unacceptable sugar. This simple paradigm works because of the Central Dogma – hammered genes are transcribed and translated into proteins whose sugar preferences might have been changed by sequence changes in the “sugar utilization” proteins.

One sees in this simple example that “faster undirected evolution with selection” approaches “directed evolution” – the differences in the end are quantitative rather than qualitative. Natural undirected evolution in bacteria, while slow, is rather extensive. We estimate that “every letter of DNA” in every bacterial species on Earth has been altered some 100,000,000 times (kind of like a metronome – first a G, then an A, then a G, then a C, then a T, and so on, 100,000,000 times) over the evolutionary history of those bacterial species (some three billion years), and thus natural undirected evolution in bacteria is complete for short stretches of their genomes. “Hammered” is an appropriate word for what has happened to bacterial genomes over time, and it is likely that the bacteria have been optimized for many physiological functions. Scientists cannot plan and execute experiments over billions of years, and thus directed evolution has emerged as the preferred way to do exhaustive genetics for a problem of interest.

The Central Dogma and “Directed” Evolution Through Selections In Vitro

High mutation rates through chemistry of DNA synthesis (above) led inexorably to directed evolution. The deep mutagenesis of DNA is a first requirement. Imagine chemical synthesis of a DNA molecule, from one end to the other, using the modern chemistry that makes such synthesis possible – one starts from one end and places into the reaction vessel first one monomer (or letter), then the second, then the third, and so on. Modern machines can easily make single-stranded DNA or RNA molecules of length 100 or more. One can put in as substrates at each step of the synthesis one activated nucleotide (ie, one letter of DNA – an A, C, G, or T) or one could, at any position, put in all four activated nucleotides and allow stochastic additions to the growing chain of any of the four nucleotides. This idea – deep mutagenesis – was powerful.

The first example of a large in vitro evolution experiment was published in 1989 by Arnold Oliphant and Kevin Struhl. The experiment they did was elegant and simple. They knew that a yeast protein (named GCN4) bound (as a transcription factor) to double-stranded DNA in a sequence-specific manner (the biology does not matter for this example). Oliphant and Struhl synthesized double-stranded DNA (how they did this is also unimportant for this discussion) containing random sequences 25 nucleotides long. That is, since they were studying 25 positions in double-stranded DNA, each containing only four letters, the total number of sequence possibilities was 4^{25} , or approximately 10^{15} . Oliphant and Struhl then asked which members of the huge combinatorial library would bind to the protein GCN4, and found a repeated sequence that allowed that binding. In principle, because of the scale of the initial synthesis, every sequence of 25 nucleotides was in their starting library many times. This first experiment was aimed at understanding a natural double-stranded DNA-binding sequence, and the experiment worked powerfully.

Directed evolution has also been aimed at proteins. Again, because the Central Dogma allows combinatorial libraries of DNA sequences to be transcribed and translated into proteins, one has access to large libraries of protein sequences. Libraries of around 10^9 protein sequences can be made and studied using in vivo methods, while larger libraries (up to 10^{15} protein sequences) can be studied in vitro. Phage display is one common way to prepare and select protein and peptide variants.

Directed evolution has been aimed at single-stranded nucleic acids through the in vitro methodologies described as SELEX (Systematic Evolution of Ligands by EXponential enrichment). Tuerk and Gold understood in 1990 that single-stranded

combinatorial oligonucleotide libraries contained large numbers of molecules with properties that went beyond linear sequence space – a “tapes versus shapes” or “strings versus things” discussion. It was of course known that many single-stranded RNAs in biology have “globular” structures – the transfer RNAs were the first to be studied by X-ray crystallography (in 1974) and shown to have an extraordinary shape. The power of SELEX lays in the vast numbers of molecules from an initial library that could be screened for a particular property. Similar selection methods also led to novel ribozymes – single-stranded RNA molecules with catalytic properties – and even novel DNazymes. Both phage display for proteins and SELEX for oligonucleotides moved toward chemistry – that is, the vast potential of directed evolution made the resulting molecules of interest (for new drugs, diagnostics, and nanomaterials) outside of the basic science questions first studied by these technologies. The molecules that were identified through SELEX were named “aptamers” by Ellington and Szostak.

In the past few decades, much emphasis has been aimed at the use of modified nucleotides to make the resulting aptamers more potent and useful for the biotech and pharma industries. The SELEX protocols include in vitro synthesis and selection of a desired oligonucleotide, and thus, one is not limited to the nucleotides found in biology. Novel aptamer reagents, called SOMAmer (Slow Off-rate Modified Aptamer) reagents, have been identified as binding reagents for more than 5000 human proteins – with more to come (there are more than 20,000 proteins in a human). The special chemistries of modified nucleotides in a short single-stranded molecule provide unique binding qualities, elucidated now in a series of four published co-crystal structures of SOMAmer reagents binding their target proteins.

The Future of Directed Evolution

The scientific, research, and medical communities have been surprised by the emergence of ribozymes/aptamers/SOMAmers as molecules with diverse capabilities. Like monoclonal antibodies, such molecules have the potential to be therapeutics or key reagents for diagnostic purposes (either in vivo, for imaging, or in vitro, for protein measurements). Directed evolution today is limited only by one’s imagination; vast combinatorial libraries can be made with unusual chemistries and special molecules can be selected from those libraries. That is, directed evolution can be directed toward many molecular properties that have not yet been sought. Novel successful selections will encourage more thinking about chemical evolution on the early earth, and widen our appreciation for the transition from a chemical earth to a self-replicating chemical earth to a biological earth, the transition that allowed undirected evolution to create numerous creatures with special adaptations to the niches in which they live. Directed and undirected evolution will inform each other in the decades ahead.

DNA Cloning Strategies[☆]

D Wall, University of Wyoming, Laramie, WY, USA

© 2019 Elsevier Inc. All rights reserved.

Glossary

cDNA Complementary DNA is a DNA copy of mRNA made by the enzyme reverse transcriptase.

Cloning The process of inserting foreign DNA into a vector. Recombinant DNA vectors are typically amplified in an *E. coli* host.

Ligation The enzymatic formation of a covalent phosphodiester bond between two nucleic acid molecules by DNA ligase.

multiple cloning sites (MCS) Short sequences engineered in vectors that contain a number of unique restriction sites for cloning DNA.

polymerase chain reaction (PCR) The enzymatic replication and amplification of DNA *in vitro*. Reactions are done in a thermal cycler with a thermostable DNA polymerase.

restriction enzymes Proteins or endonucleases that cleave phosphodiester bonds in DNA at specific sequences.

Screen The process of visually inspecting mutant or transformed organism for altered phenotypes. In cloning, blue/white screens are commonly employed to identify clones with insert DNA.

Selection The process of forcing a cell to contain a desired phenotype and genotype. For example, plasmid uptake by bacteria can be selected for by antibiotic resistance.

synthetic DNA The ability to chemically make DNA *de nova* in the absence of a template or a polymerase.

Transformation The process of introducing new or recombinant DNA into an organism. Some bacteria are naturally transformable. Most bacteria require artificial methods, chemical or high-voltage (electroporation), to compromise cell permeability for DNA uptake.

Vectors DNA vehicles that allow foreign DNA to be combined in new ways and amplified. Vectors encode *cis* elements to initiate DNA replication (*ori*), site to insert foreign DNA (MCS) and contain a selectable marker, such as antibiotic resistance. Vector examples include plasmids, cosmids, BACs and YACs.

Cloning Strategies

At the heart of recombinant DNA technology is how different molecules are joined or ligated together. Specifically, the nature of the 5' and 3' ends of each DNA molecule is important for covalent bond formation. DNA ends can be mechanically created by shearing or sonication forces. Such techniques create random breaks in DNA that are useful for cloning genomic libraries. Physical forces break different chemical bonds and produce heterogeneous or damaged ends. To allow efficient cloning these ends are enzymatically repaired with DNA polymerase or exonuclease treatment to produce 'polished' blunt ends. Alternatively linear DNA molecules are generated with precise ends by PCR or restriction digestion. In most cases the underlying cloning strategy is relatively simple, but in practice there are numerous steps and the process can be difficult. Thus when designing and conducting a cloning experiment attention to detail is essential for success.

PCR Based Cloning

There are many ways to clone DNA. Over the past two decades, great strides have been made in sequencing whole genomes. As a result investigators frequently know the sequence of their target DNA for cloning. This information is invaluable and allows one to easily amplify target DNA by PCR (Figure 1). A power of PCR cloning is that the DNA or gene of interest (GOI) can be directly and precisely amplified from biological material or cell cultures. One does not necessarily need a pre-existing clone or even purified genomic DNA material, though such preparations do facilitate PCR amplification. As shown, to amplify the GOI two primers are designed that specifically hybridize with template DNA. Primers are routinely synthesized at research institutions or are readily available through commercial vendors at an economical price. An additional advantage of PCR cloning is that desired DNA sequences can be engineered into primer sequences. For example, to facilitate cloning primers are designed with unique restriction sites in their 5' tails that do not interfere with priming at the 3' end (Figure 1). After amplification the PCR products contain incorporated restriction sites. To clone the PCR products they are digested with restriction enzymes. Plasmid DNA is digested with the same enzymes producing complementary sticky ends that can anneal by forming hydrogen bonds with insert DNA. These two DNA fragments are covalently bonded with DNA ligase. The ligated plasmids are transformed into an *E. coli* host by selecting resistance to the antibiotic kanamycin. Transformant clones are screened to identify clones with the correct insert DNA.

[☆]Change History: August 2014. D Wall introduced small edits in the text of the article including citations, added the sections "Applications" and "References" and added Figure 6

This article is an update of D. Wall, Recombinant DNA, Basic Procedures, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 271–280.

Figure 1 PCR cloning strategy. Two primers are designed to specifically amplify the 5' and 3' end of a gene of interest (GOI). These primers include restriction sites (green) engineered in the 5' tails. The vector DNA is digested with the same enzymes within the MCS (arrowhead). The DNA is ligated generating a recombinant plasmid that is transformed into *E. coli* selecting Kan^r.

A number of technologies have simplified and reduced the time it takes to construct recombinant clones. Central to this development is PCR and the rapid pace of genome sequencing. Consequently a key part on cloning involves primer design. Primer design essentially has two parts. First, primers are optimized for robust and specific amplification of the target DNA. Key parameters to consider are primer length, melting temperature, avoiding secondary structure within and between primers and ensuring the 3' end is specific toward target DNA. Primers can be manually design, but commercial or web-based computer algorithms work better and faster. In some cases there are few choices in design because a primer needs to start at specific sequence, e.g. beginning or end of a gene. The second factor to consider is engineered sequences. For example, a particular mutation can be incorporated into a primer. Alternatively, restriction sites or epitope tags are included. In other cases degenerative primers might be sought to amplify gene homologs. In sum, the ability to engineer any sequence into a primer provides tremendous latitude to make unique recombinant DNA molecules and to simplify complex cloning steps.

Investigators that rarely employ or want to shorten cloning steps may consider a number of products that simplify the process. One technology is called TOPO cloning (Life Technologies). The advantage of TOPO cloning is that PCR products are efficiently and directly cloned into commercially prepared vector reaction that is ready for ligation. Here, the linearized vector has been prepared with Vaccinia virus topoisomerase I covalently attached to each 3' end. Addition of insert DNA with free 5' ends allows rapid ligation to the vector catalyzed by topoisomerase I. This technology has also exploited the unique activity that thermophilic *Taq* DNA polymerase adds a single deoxyadenosine (A) to the 3' ends of PCR products. Thus some of the TOPO cloning kits include linearized plasmid DNA that has complementary 3' deoxythymidine (T) overhangs covalently bonded to topoisomerase I. Other TOPO vectors are prepared for blunt end cloning. Significantly, neither the PCR product nor the plasmid needs to be restricted or purified for ligation. Instead material directly from the PCR reaction is mixed with prepared TOPO vector. The ligation is completed in 5 minutes and is ready for transformation. TOPO vectors are available in a variety of configurations. Thus in many cases an ideal vector is found and eliminates subsequent cloning to make the desire construct.

Restriction Endonucleases

Restriction endonucleases are enzymes that recognize specific DNA sequences for cleavage. These enzymes have formed the backbone of recombinant DNA technology. Stanley Cohen, Stanford University, and Herbert Boyer, University of California, San Francisco, and colleagues first published a cloning experiment in 1973. Here they used *EcoRI* to digest two plasmids, pSC101 and

pSC102, to form a new recombinant plasmid that contained the tetracycline and kanamycin resistant markers from each parent plasmid. Today investigators no longer need to purify their own restriction enzymes, but instead chose from around 300 commercially available endonucleases. Most restriction enzymes used for molecular cloning are Type II that cleave within or adjacent to the recognition sequence. Type I and Type III restriction enzymes, which also contain DNA modification activity, are rarely used for cloning. The names of restriction enzymes begin with the first letter of the genus followed by two letters from the species name from which they were isolated. This abbreviation is followed by numbers or letters that typically refer to more specific strain information or order of isolation. Some restriction enzymes also have a corresponding commercially available DNA methylases. These enzymes recognize the same DNA sequences as their cognate restriction enzyme and block DNA cleavage by methylation.

The length of DNA that restriction enzymes recognize varies, though most enzymes recognize 4 or 6 base pairs (bp). The frequency of tetranucleotide sites appear once every 256 bp (4^4), while a hexanucleotide site appears once every 4096 bp (4^6). The frequency of sites within the DNA is also influenced by G+C content. Most restriction sites have dyad symmetry: the double stranded sequence is identical after 180° rotation. The decision on what particular restriction enzymes to use partly depends on the size of DNA sought. To prepare a plasmid for cloning one typically uses a 6-cutter, since a 4-cutter would generate too many fragments. Along with generating smaller DNA fragments, 4-cutters are useful to generate a relatively random pool of larger DNA fragments by a partial digestion. The size of the DNA fragment pool is controlled by simply changing incubation times. For this reason genomic libraries are often constructed with 4-cutter enzymes. Other restriction enzymes recognize longer sequences, such as 8 bp, and consequently rarely cut DNA.

Another important distinction among restriction enzymes is the type of ends they produce. Some enzymes cleave each strand at similar locations of the opposite sides of the axis of symmetry, creating ends that carry protruding single-stranded cohesive or “sticky” termini. Depending on the restriction enzyme either 5′ or 3′ protruding ends are produced (Figure 2). Other enzymes cleave both strands exactly at the axis of symmetry, generating blunt ends, e.g. *SmaI* (Figure 3). All cleavage reactions produce 5′ phosphate and 3′ hydroxyl ends, both of which are required for ligase to produce a recombinant DNA molecule.

Figure 2 illustrates the details of how two DNA molecules are cut by the *SalI* and *XhoI* restriction enzymes. Both enzymes recognize specific 6 bp sequences that have dyad symmetry. The digested DNA fragments contain 5′ protruding sticky ends. Although these restriction enzymes recognize different DNA sequences the core 4 bp are identical. Consequently the 4 bp 5′ protruding ends are the same and are annealed and ligated. Figure 2 shows the resulting 6 bp sequence that neither *SalI* nor *XhoI* recognize, though the core 4 bp sequence remains and contains a *TaqI* 4-cutter recognition site. This is one of many examples of how different restriction enzymes can produce ends that are compatible for ligation. Such ligated ends may also produce new restriction sites for use in a subsequent cloning step.

Figure 3 outlines a more complex cloning scheme. Here, insert DNA was cleaved with *EcoRI* to generate 5′ protruding sticky ends, while vector DNA was cut with *SmaI* to generate blunt ends. In order to clone the insert DNA into the vector’s *SmaI* site it must be blunted. 5′ overhangs can be blunted by a T4 DNA polymerase fill-in reaction (Figure 3) or by removal of overhangs with mung bean exonuclease. If the foreign DNA was instead digested with an enzyme that produced 3′ overhangs it would have to be blunted by an exonuclease (mung bean or T4 polymerase which contains 3′ to 5′ exonuclease activity). Since blunt end ligations do not

Figure 2 Restriction digestion and ligation. The restriction sites have dyad symmetry. Both digestions produce 5′ protruding ends that are identical and complementary for sticky end ligation. One end of the ligated product is shown and generates a new site that neither *SalI* nor *XhoI* recognize, but does contain the site for the *TaqI* 4-cutter restriction enzyme (box).

Figure 3 Outline of a blunt end cloning strategy. Insert DNA is digested with *EcoRI* which produces 5' overhangs. T4 DNA polymerase treatment results in filled-in blunt ends. Vector DNA is cleaved with *SmaI* that produces blunt ends. To prevent vector self-ligation it is treated with alkaline phosphatase to remove 5' phosphate groups. Only ends with 5' phosphate and 3' hydroxyl groups can ligate, resulting in a nicked ligation product.

contain annealed sticky ends they are less efficient. To improve the frequency of recovering ligation products with inserts the vector DNA is treated with alkaline phosphates to remove the 5' end phosphates (Figure 3). Consequently the vector cannot self-ligate, however the vector can ligate to blunt end inserts that contain phosphorylated 5' ends. Thus at each ligated end the DNA contains one ligated strand and one nicked strand (Figure 3). Once transformed into *E. coli* the host machinery will repair the DNA nicks. Though phosphatase treatment involves an extra step and reduces ligation efficiencies, the procedure helps to ensure the desired is obtained. Another strategy to prevent vector self-ligation is to cut vector and insert DNA with two different restriction enzymes that produce ends that are not compatible for annealing. This highly efficient cloning method forces the insert DNA to be directionally cloned, since the insert is only annealed in one orientation. This method is frequently employed as most vectors contain MCS and clones are often sought in a particular orientation so, for example, they can be expressed from a vector based promoter.

Homology based and Site-Specific Recombination

Restriction enzymes and DNA ligase have formed the foundation of recombinant DNA. However today there are other strategies to recombine DNA into new purposeful configurations. TOPO cloning described above is one such example. Another recently developed strategy is called Gibson cloning. This method is named after one of the inventors, Daniel Gibson, and is powerful because multiple DNA fragments can be simultaneously assembled into a plasmid. This is possible by the use of a cocktail of enzymes, which includes an exonuclease to create single-stranded 3' overhangs that facilitates annealing of ends that are complementary. The cocktail also includes DNA polymerase to fill in the gaps within each annealed fragment and DNA ligase to seal the nicks and assemble a recombinant clone. For the reaction to work the enzymes must be present at appropriate concentrations. Toward this end commercial cocktails are available (New England Biolabs Inc.). A further utility of Gibson cloning is that different DNA fragments can be seamlessly assembled. To assemble the fragments complementary ends can be made by primer design and PCR.

Another cloning strategy is called GATEWAY cloning (Life Technologies), which relies on bacteriophage λ site-specific recombination system that integrates the phage genome into the *E. coli* chromosome. In this system neither restriction enzymes nor DNA ligase is used to form recombinant molecules. Instead engineered vectors act as donor (entry) and recipient (destination) substrates for subcloning between plasmids. The donor plasmid contains a GOI flanked on both sides by the *attL* sequence, while the recipient plasmid contains a counter-selectable marker (*ccdB*) flanked on both sides by *attR* sequences. These plasmids are mixed in vitro with the *Int*, *Xis* and *IHF* enzymes that catalyze site-specific recombination between the *attR* and *attL* sequences. The recombination product contains the GOI in the recipient plasmids flanked by the recombined *attR/attL* sequence (*attB1*), while the *ccdB* gene now resides in the donor plasmid flanked by *attP* sequences ('by-product' plasmid). The reaction mixture is transformed into *E. coli* selecting the desired antibiotic resistance, while the original donor and by-product plasmids are selected against because of the toxic

ccdB gene product. This reaction is analogous to phage λ excision from the *E. coli* chromosome. The reverse (integration) reaction is performed by assembling the same reaction, but excluding the Xis protein. The utility of the GATEWAY system is that a GOI can quickly and efficiently be subcloned into a wide range of vectors for genetic or protein expression studies.

In an alternative strategy, plasmid DNA can be recombined *in vivo*. One system relies on homologous recombination techniques in *E. coli* to swap pieces of DNA between different plasmids ('MAGIC'). In short a donor plasmid is transferred by conjugation, bacterial mating, into a recipient strain that harbors a recipient plasmid. Both plasmids are engineered with homology regions and I-SceI sites that flank the regions to be recombined. Upon induction in *E. coli* of the I-SceI restriction endonucleases, which recognizes an 18-bp sequence, and the bacteriophage λ -red *gam* gene products (recombinase), the target DNAs are excised and the linear products are homologously recombined *in vivo*. The desired chimeric plasmid is then selected for *in vivo* (antibiotic resistance and counter selection techniques).

DNA Synthesis

DNA can be chemically synthesized *de nova* in the laboratory. A key advantage for using DNA synthesis is that any sequence can be easily and quickly made. For this core technology molecular biologists typically rely on commercial vendors or core nucleic acid facilities at larger research institutes. In the case of oligonucleotide synthesis, which is typically used as primers for DNA synthesis or as probes, this technology has been available for several decades at a reasonable cost. Here oligonucleotides, typically 15 to 100 bases long, can be embellished with desired restriction sites or with tag sequences. A tag can encode a motif to facilitate protein purification or an epitopes to assist with protein detection. Oligonucleotide synthesis also allows primers to be easily made for use in site directed mutagenesis. In summary, oligonucleotide synthesis has great flexibility in the construction of recombinant DNA molecules.

In the past few years the technology to synthesize large DNA molecules has significantly improved, while the costs have also dropped. At the time of writing of this review commercial vendors can synthesize DNA from 100 to 10 000 bp. At a price of about \$0.30 bp⁻¹ a typical sized gene of 1000 bp can be synthesized and cloned at a reasonable cost. These developments have several important implications. First, in many cases it is more time and cost effective to have a desired gene or DNA molecule synthesized than for a researcher to make it themselves by standard recombinant DNA methods. For example, if one is interested in a particular gene found in a database, but the genomic DNA is not in the laboratory, they can simply have it synthesized, instead of requesting or ordering the template DNA for PCR based cloning. Second, for investigators that are not familiar with cloning approaches they can circumvent this problem by simply ordering the desired clone. Third, the ability to synthesize DNA *de nova* allows one to create or optimize any sequence they want. For example, to maximize recombinant protein expression in a heterologous host, codon usage can be optimized for that host. Alternatively, if one wants to introduce restriction sites, tags, mutations, create chimeras or any combination thereof; they can easily do so by having their optimized gene synthesized. Additionally, these changes can be seamlessly made without leaving scars in the DNA, which sometimes occurs using standard cloning methods. Because of these advantages, even highly skilled molecular biologists will sometimes prefer a synthetic DNA cloning strategy over multi-step cloning approaches.

Clone Isolation and Characterization

After recombinant DNA molecules are made *in vitro* and transformed the correct clone must be isolated. Two general methods for clone identification are genetic selections and screens. Selection is preferred because it demands an essential activity for cell survival and allows rapid and rare clone isolation. For example, the cloning of the tetracycline resistant marker is easily selected for by growing transformed cells on tetracycline plates. This strategy allows a rare Tet^R marker to be readily cloned from genomic DNA. Such techniques are commonly used to isolate genomic DNA linked to a transposon marker. Similarly, if a strain contained a temperature sensitive mutation in an essential gene, such as DNA gyrase, the corresponding wild type gene can be readily cloned from a genomic library by selecting growth at a non-permissive temperature. Although cloning by selection is powerful it is not infallible. In this latter scenario, complementing candidate clones may include DNA gyrase as well as other genes that function as multicopy suppressors of the temperature sensitive mutation. Frequently, selection strategies are not available and one resorts to screening. α -complementation allows a quick blue/white screen for insert clones and is described below. If selections or phenotypic screens are not available then molecular techniques are employed. Common techniques include diagnostic colony PCR or restriction analysis. These methods are more labor intensive, but are always available for clone validation. If a very rare clone is sought, for example one gene out of a genomic library, then methods such as colony hybridization may be employed. Here colony libraries are transferred to membranes and screened with labeled (radiolabeled, bioluminescent, etc.) probes (e.g. nucleic acid or antibody) to identify a specific DNA, RNA or protein clone.

As mentioned, part of the cloning process includes clone characterization. To do this there are a number of available methods to extract and purify vector DNA. Two common protocols are extraction by alkali or boiling lysis of *E. coli* cells. These steps selectively release plasmid DNA from large chromosomal DNA that is trapped and precipitates with lipids and cell wall debris. Vector DNA is further purified by selective precipitation of proteins or organic extraction with phenol and chloroform. RNA is removed by RNase treatment. Ethanol precipitation allows quick concentration of DNA from solution. Plasmid DNA can be further purified by ultracentrifugation in a cesium chloride (CsCl) density gradient with ethidium bromide. This procedure results in a highly purified band of supercoiled plasmid DNA in the CsCl gradient. In lieu of these time-consuming procedures commercial plasmid purification kits, which selectively bind DNA to membranes, are available from a variety of vendors. Once purified, vector DNA is characterized by restriction digestion or PCR, followed by agarose gel electrophoresis separation and visualization with ethidium bromide staining.

Figure 4 Agarose gel electrophoresis and ethidium bromide staining of DNA samples. Lane 1 is a commercial DNA ladder used as molecular weight standards. Selected sizes are shown at the left. Lane 2 and 3 are PCR products with predicted sizes of 522 and 623 bp, respectively. Image kindly provided by Yao Xiao.

Electrophoresis of DNA through an agarose gel is a standard and rapid method to separate DNA fragments based on size. Commercially available agarose is derived from seaweed and composed of polysaccharide and galactose sugars. The dynamic range for size separation is easily adjusted by changing the agarose concentration. DNA migrates through pores in the gel in response to an applied electric field. Migration occurs from negative to positive potential due to the net negative charge of the phosphate backbone. A representative agarose gel is shown in Figure 4. Following electrophoresis the bands were stained with ethidium bromide which intercalates in the DNA helix. The bound ethidium bromide is fluorescently visualized by ultraviolet light exposure. Cloned DNA can be further characterized by Southern blot analysis. In this method DNA is transferred or blotted from a gel onto a nitrocellulose or nylon membrane which is then hybridized with a labeled nucleic acid probe. For high resolution DNA separation, for example to resolve single base differences, agarose is substituted with polyacrylamide. The exact base composition of cloned DNA can be determined by sequencing reactions and resolution on a polyacrylamide gel. Obtaining the DNA sequence is important to conduct homology searches and to predict protein functions and study evolutionary relationships between sequences. The DNA sequence also facilitates clone construction to identify restriction or primer sites. Due to low costs, today most labs use core facilities or commercial vendors for DNA sequencing.

Subcloning

Sometimes the original GOI clone will be derived from a vector used to clone large DNA fragments or cDNAs and is not suitable for subsequent studies. For example, a researcher might want to study gene expression and protein localization in the original host organism and might separately want an expression vector for protein purification. Each of these experiments will likely require different promoters, replicons and selectable markers. Consequently the GOI needs to be subcloned into different vectors to address specific experimental needs.

Protein expression

A common recombinant DNA objective is the overexpression of a target protein. Overexpression is achieved in a wide variety of expression vectors. Once validated clones are constructed they are assessed for overexpression. In some cases overexpression is phenotypically observed, such as the ability of a cell to produce the green fluorescent protein. However, typically expression is evaluated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). If overexpression is significant the protein product is directly visualized upon coomassie blue staining. If expression is modest and not readily detected by SDS-PAGE then other more sensitive methods are employed.

The T7 RNA polymerase/promoter system is both a powerful and sensitive system for expression and detecting recombinant proteins. The two key factors of the system are: (i) T7 RNA polymerase is highly selective and consequently does not recognize any *E. coli* promoter. Only the recombinant gene fused to the vector T7 promoter is expressed. (ii) The antibiotic rifampicin selectively inhibits host RNA polymerase and does not inhibit T7 RNA polymerase. Thus when a host cell is induced to express T7 RNA polymerase and then treated with rifampicin the only promoter that is transcribed is vector borne. If cells are grown in minimal media and given radiolabeled [^{35}S] methionine shortly after rifampicin treatment the only protein labeled in the cell is from the T7 promoter. Selective protein labeling is the result of rapid mRNA degradation in *E. coli*. Subsequently, proteins are separated by SDS-PAGE and visualized by autoradiography. Alternatively, commercial coupled *in vitro* transcription-translation systems allow selective expression and labeling of genes contained in a purified plasmid.

Western blot analysis is yet another sensitive method to detect recombinant proteins. In many cases commercial antibodies are available that selectively bind target proteins or are cross-reactive. If antibodies to the native protein are not available then an epitope tag can be fused in-frame to the recombinant protein at the amino- or carboxyl-terminus. A variety of commercially available antibodies detect these epitopes by Western blot or ELISA (Enzyme-Linked ImmunoSorbent Assay).

In some cases *E. coli* is not a suitable host for the expression of recombinant proteins. Complicating factors include: unstable or unfolded or aggregated proteins, low expression levels or lack of proper post-translational modification such as glycosylation. Some of these problems are addressed by changing strain background or growth conditions. In other cases the gene needs to be subcloned into a shuttle vector for expression in a different bacterial or eukaryotic host. Another factor that affects expression levels is codon use. Since each species has its own preferred codon set, a foreign gene will likely not contain optimal codon preference for high expression. To circumvent this problem a gene can be synthetically made with optimal codon use for the intended host. Depending on gene size this can be an expensive endeavor, but is done for highly sought proteins, such as those with commercial applications.

Cloning Vectors

Cloning vectors have three common properties: (i) a selectable marker, which is almost always antibiotic resistance; (ii) an origin of DNA replication to allow vector propagation; and (iii) MCS or polylinker that contains a number of restriction sites to clone foreign DNA. Vectors also frequently contain other elements to assist cloning. For instance, a facile way to screen clones for insert DNA is important. Typically this can be screened by loss of an antibiotic resistance marker, insertional inactivation, or α -complementation with β -galactosidase (below). Vectors may also contain regulatable promoters to express a GOI. Expression vectors typically also contain a transcriptional terminator immediately following the MCS to prevent transcription of downstream DNA. Some plasmids contain an origin of replication for filamentous phage such as M13. When a helper phage is added the cloned DNA is packaged as single-stranded DNA in bacteriophage heads. This DNA serves as template for sequencing.

Plasmids

The preferred cloning vehicles are plasmids, because high quantities of vector DNA are rapidly purified and they are typically small. Both of these factors are important because they allow easy manipulation and characterization. Small plasmids, 3 to 4 kilobase pairs (kb), are ideal because they contain relatively few restriction sites and are efficiently transformed into host cells. Small plasmids are less likely to contain multiple restriction sites and thus are more readily interpreted on agarose gels. In contrast, large vectors may require extra steps that involve autoradiography methods to characterize clones. Practically, the efficiency of transformation significantly decreases as plasmid size exceeds 10–15 kb. This is especially critical when ligations are transformed.

Plasmid copy number varies greatly depending on replicon use. Low copy or stringent replicons such as the F plasmid have 1–2 copies per cells. Low copy replicons are ideal to clone toxic DNA to ensure tight gene repression and maintain plasmid stability. Medium copy number plasmids exemplified by the ColE1 and pMB1 (pBR322 and derivatives) replicons are maintained at about 15–20 copies per cell. High copy number plasmids, typified by the pUC vectors, are maintained around 500 copies per cell and are said to replicate in a “relaxed” (not stringent) fashion. Initiation of replication in the widely used pMB1 and ColE1 replicons is primed by an RNA primer. This primer hybridizes to the template DNA near the *ori* and is processed by RNAase H into a mature form (RNA II) to prime plasmid replication. The activity of RNA II is in turn regulated by RNA I, which is plasmid encoded on the opposite strand of the *rna II* gene. The binding of RNA I to RNA II prevents RNA II priming. The pairing of these RNAs is enhanced by a plasmid encoded protein called Rop, which reinforces the negative regulation of RNA I and reduce plasmid copy number. The copy number of pMB1 or ColE1 plasmids can consequently be increased by mutations in *rop* or *rna I*. Thus, for example, the popular pUC derived plasmids are high copy pMB1 replicons that contain a *rna I* mutation that impairs plasmid copy number control resulting in elevated levels of plasmid.

In addition to controlling copy number, RNA I, II and Rop determines the plasmid compatibility group. Plasmid compatibility groups are important when two different plasmids are sought in the same host cell. When two different plasmids belong to the same incompatibility group, such as the pMB1 and ColE1 replicons, they become unstable in the same cell. In this case the same copy control mechanism regulates both plasmids; that is copy number of both plasmids is the same as a single plasmid. Since the plasmid partitioning is not regulated in these vectors, there is a stochastic distribution of plasmids into daughter cells. Over time and cell divisions the ratio of plasmids varies and one is eventually lost. In contrast, the pMB1 and ColE1 replicons are compatible with p15A (pACYC and derivatives) and pSC101 replicons and are stably maintained together.

Most plasmids do not require synthesis of plasmid encoded proteins for replication. They instead rely on long-lived host enzymes for replication, while the host requires continued protein synthesis for chromosomal replication. Plasmid DNA yields are accordingly increased by up to 50-fold by treating late log cultures with translation inhibitors such as chloramphenicol. This treatment efficiently blocks chromosomal replication and enriches plasmid recovery.

Recombinant DNA tools and methods have primarily been developed and optimized for *E. coli*. Thus regardless of the organism that one is studying the initial cloning experiments are usually done in this host. However, investigators frequently study biological process in other species, whether eukaryotic or prokaryotic, and as a result need to move their vector into those cells. Since many of the *E. coli* plasmid genes or genetic elements do not function in distantly related hosts, the use of shuttle vectors is employed. Shuttle vectors contain two replicons and replicate in two different hosts. A mammalian shuttle vector, for example, may contain an adenovirus

replicon to allow mammalian cell replication. In other cases a vector might not replicate in the host cell but instead recombine into the genome by homologous or site specific recombination. Still other vectors are not stably maintained in their host, e.g. transient transfections. Aside from the replicon, other genetic elements, such as selectable markers and promoters, need to be suited for the intended host. For all of these reasons and more there are literally thousands of different vectors used by molecular biologists.

Bacteriophage, Cosmid, BAC and YAC Vectors

When large pieces of DNA are cloned other vectors beside plasmids are typically used. One alternative vector that was developed early in recombinant DNA evolution was bacteriophage λ . In phage λ it was recognized that much of the nearly 50 kb genome was dispensable for lytic growth and thus suited for replacement with foreign DNA. To construct a λ clone or libraries, insert fragments of approximately 20 kb are ligated to the left and right arms of λ genomic DNA that had been restricted and purified. Ligated DNA is then packaged with two complementary *E. coli* strain extracts infected with different λ mutants that cannot replicate or package their own DNA. The physical requirement that DNA molecules with λ *cos* sites, 12 bp single stranded complementary ends of the linear genome, be separated by approximately 50 kb for packaging provides a strong selection for inserts of a given size. A variety of λ vectors are available with different cloning sites and accommodate different insertion sizes or allow expression of cloned DNA. Advantages of λ vectors include large insert cloning and phage amplification. Because the host cell is killed during lytic growth toxic or unstable DNA fragments may be better suited in λ vectors.

Cosmid vectors are plasmids containing the λ *cos* site. Cosmids allow relatively large DNA fragments, 30–45 kb, to be cloned. Ligated recombinant cosmids are packaged in λ phage heads by *in vitro* packaging with cell extracts. A phage particle is produced which is transduced into *E. coli*. Transductants are selected by antibiotic resistance encoded on the autonomously replicating cosmid. Still larger DNA fragments, 100 to 300 kb, are cloned into bacterial artificial chromosomes (BACs). The BAC is based on the F plasmid replicon and partitioning system which maintains 1–2 copies per cell. Thus foreign DNA is simply ligated into the BAC vector and optimized electroporation conditions transform the BAC into *E. coli* by selecting antibiotic resistance. Because of the low copy number BACs are stably maintained and the supercoiled DNA it is relatively easy to purify and manipulate. Yeast artificial chromosome (YAC) vectors can accommodate 100 to 1000 kb of foreign DNA. These linear vectors contain a centromere, replicon, telomers and selectable marker which are ligated *in vitro* DNA of interest and transformed into yeast. Although very large fragments are cloned, YAC clones are unstable and difficult to manipulate.

E. Coli Host

E. coli generally serves as the host cell when constructing recombinant clones. However, there are exceptions to this rule, for example YACs are directly transformed into yeast. There are similar examples in other bacteria. In most cases, however, *E. coli* serves as the host for constructing recombinant clones because of its: (i) high electrocompetent transformation efficiencies ($>10^{10}$ transformants per μ g DNA) or rapid chemical competent protocols, (ii) fast high density growth, (iii) availability of advance genetic tools, such as regulatable promoters, (iv) there are a plethora of established academic and commercial vectors available for cloning, and (iv) in-depth understanding of *E. coli* genes and biology important for cloning.

When selecting an *E. coli* host strain for cloning there are a number of genetic variables to consider. First, like many bacteria, *E. coli* contains host restriction modification systems to destroy foreign DNA. The *EcoK* I restriction system, encoded by *hsdRMS*, cleaves DNA that is not protected by adenine methylation at the ACC[N6]GTGC or GCAC[N6]GTT sites. A *hsdR* mutation abolish restriction but not methylation ($r^{-}m^{+}$), while *hsdS* mutations abolish both ($r^{-}m^{-}$). In contrast, the *mcrA*, *mcrBC* and *mrr* genes encode methylation requiring systems to attack DNA only when it is methylated at specific residues. All three of these endonucleases restrict DNA modified with CpG methylation. Thus when cloning DNA from mammals, plants and some bacteria it is wise to use strains that lack the *Mcr* and *Mrr* systems.

DNA methylation systems in *E. coli* can affect the susceptibility of cloned DNA to subsequent restriction analysis. Strains that encode a functional *dam* gene methylate DNA at GATC sites, while the endogenous *dcm* gene product methylates CC(A/T)GG sequences. In some cases restriction enzyme cleavage is blocked by Dam or Dcm methylation, e.g. *Clal* and *StuI*, while in other cases restriction site methylation does not block cleavage, e.g. *BamHI* and *KpnI*.

There are a number of other factors to consider when selecting a host *E. coli* strain for cloning. If the cloned DNA has high homology to the host chromosomal DNA, e.g. an *E. coli* gene, or to sequences within the clone, such as repeat elements, it might recombine in undesirable ways. To avoid this problem select a strain with a *recA* mutation that abolishes homologous recombination. Mutations in *endA*, which encodes endonuclease I, blocks nonspecific degradation and yields high quality cloned DNA that is not nicked or degraded. If a high copy plasmid is unstable, presumably by expression of a toxic product, it can be stabilized by a *pcnB* mutation, which reduces the copy number of the popular ColE1-type plasmids. If expression of a recombinant protein is unstable it may be stabilized by mutations in *lon*, *clpP* or *rpoH*, all of which reduce cellular protease activity.

Certain strains of *E. coli*, e.g. DH5 α , have been constructed to optimize transformation efficiencies and clone identification. A common tool to rapidly identify clones that contain insert DNA is the use of α -complementation. Vectors that allow α -complementation contain a short 146 amino acid fragment of the *E. coli* β -galactosidase gene (*lacZ*). This DNA fragment is typically embedded in the polycloning site. When expressed this amino-terminal α -complementation fragment can associate in appropriate strains that contain a ω fragment derived from the carboxyl-terminal portion of β -galactosidase. These Lac $^{+}$ bacteria are

easily recognized as blue colonies in the presence of chromogenic substrate 5-bromo-4-chloro-3-indolyl- β -D-galactosidase (X-gal). However, when foreign DNA is cloned into the MCS the α -complementation fragment is destroyed and the recombinant clones appear as white colonies. This simple screen allows quick identification of candidate recombinants.

There are a number of other factors that one should be mindful of when selecting an *E. coli* host for cloning. For example, the construction of many strains of *E. coli* has resulted in the placement of drug resistance markers in the chromosome. In some cases these are drug resistant cassettes, such as tetracycline or kanamycin resistance. In other cases mutations in host genes, for example *rpsL* mutations, confer antibiotic (streptomycin) resistance. To select transformants the host must not contain the same antibiotic resistant marker as the vector. Another consideration is whether the host contains the appropriate transcription factors to regulate expression of cloned DNA. For example many vectors contain the *lac* promoter/operator and thus to repress gene expression the host needs to encode the Lac repressor (*lacI*). The Lac repressor is allosterically inactivated by isopropyl β -D-1-thiogalactopyranoside (IPTG) and triggers expression of the *lac* operon. The popular pET vectors contain the bacteriophage T7 promoter and in order to drive transcription the T7 RNA polymerase gene needs to be encoded in the host.

Applications

Recombinant DNA has revolutionized biological research and has had huge impact on the pharmaceutical and biotechnology industries. These techniques have provided the foundation for sequencing the human genome and hundreds of other genomes by providing genomic libraries. This information is invaluable for the molecular understanding of how cells and organisms function. Genomic sequence information allows a clear understanding of evolutionary relationships between species and genes. Genomic information also allows an understanding of how the environment impacts cellular physiology and genetic composition. This is particularly true with microorganisms as they are found in a plethora of environments; e.g. soils, oceans, streams and animal and plant hosts. These environmental conditions can vary greatly with respect to temperature, pH, osmolarity, oxygen tension, radiation levels or nutrient availability. Knowing the genomic sequence of bacteria found in different environments provides a molecular understanding how genes and organisms adapt to their environment.

In the pharmaceutical industry recombinant DNA methods are common tools used in drug discovery and development. These techniques help to find and elucidate interactions between therapeutic compounds and target macromolecules such as protein or RNA. Potential effects on cellular physiology, toxicologically along with mechanism of compound action and resistant profiles can be tested with molecular genetic or biochemical methodologies. Natural product therapeutics, derived from microbial secondary metabolites, are optimized by recombinant methods to improve yields or alter chemical structures.

The biotechnology industry uses recombinant DNA to isolate, improve and produce protein therapeutics such as insulin, human growth factor, interferon, erythropoietin (Epogen) and filgrastim (Neupogen). Many other therapeutic recombinant proteins are clinically used or under development. Recombinant DNA technology has also resulted in improved vaccines that simply contain isolated antigen and no other bacterial or viral component that often leads to adverse side effects. In agriculture recombinant DNA has improved plant growth by increasing nitrogen fixation efficiencies, by cloning bacterial genes and inserting them into plant cells. Other plants have been engineered to be resistant to caterpillar, pests and viruses by inserting resistant genes into plant genomes. In humans gene therapy may one day improve health. Here cells are removed and transformed with altered genes and replaced back into the patient to provide missing functions. Alternatively, recombinant viruses or other methods could be used for gene therapy delivery in live hosts. Gene therapy has the potential to replace drug therapy, which takes many years to develop safe and efficacious molecules for treating human genetic disorders. Lastly, recombinant DNA methods are used to isolate, develop and purify catalytic enzymes used in industrial processes. Enzymes have practical implications in many chemical synthesis processes by improving the rate and specificity of reactions. Such enzymes are used for pulp bleaching in paper making, oil processing, household detergent ingredients and conversion of biomass or oils into ethanol or biofuels.

In forensic science, recombinant DNA techniques help law enforcement agencies test relationships between biological crime samples and individuals to prove guilt or innocence. These methods are also used to understand family heredity and to screen individuals for the presence or absence of genetic diseases. One technique is DNA fingerprinting by restriction fragment length polymorphisms (RFLP). Here unique repeating DNA sequences in individuals are characterized by restriction digestion analysis in which specific bands on blots are probed with labeled nucleic acids. Alternatively, polymorphisms can be identified by high throughput DNA sequencing methods.

In biological research recombinant DNA methods are omnipresent. They are used to study gene function by constructing mutant alleles to test phenotypes. Site-specific mutations are readily engineered into primers used in PCR amplification. This approach is particularly attractive when structural information is available or evolutionarily conserved sequences/motifs are found within proteins. Thus site-specific changes in gene sequences directly test structure-function relationships. Alternatively random mutagenesis of a cloned gene is used in an equally informative and unbiased approach to study gene function. DNA regulatory elements, such as promoters, can be studied *in vivo* by fusing them to reporter proteins, such as β -galactosidase. These reporters are used to test gene expression responses to environmental or cellular changes. Reporters can be conveniently vector encoded or integrated into the chromosome to allow accurate physiological measurements. Subcellular localization of proteins is visualized by fusing a gene product to a reporter, such as the green fluorescent protein, and observed by fluorescent microscopy. Regulatable expression vectors allow a gene product or alleles thereof to be conditionally expressed in cells. Such systems test biological responses to gene products or provide a means protein overexpression.

When biochemical methods are used to study biological processes the investigator may identify protein product before the gene is known. In these cases reverse genetics is used to isolate the corresponding gene and to construct mutants to study protein function *in vivo*. Here the partial protein amino acid sequence is determined. With this information a degenerative DNA sequence is deduced for every combination of codons to each amino acid. If the genome sequence is available the corresponding gene is found with bioinformatic tools. If the genome sequence is not available then degenerative oligos are synthesized to the peptides and a gene fragment is PCR amplified. Alternatively, the oligos (or PCR product) is labeled as a hybridization probe to identify the corresponding clone from a genomic library. Recombinant DNA and genetic techniques provide the means to insert mutant alleles into the host to study mutant phenotypes. Depending on the genetic tools available for a host a variety of mutants can be constructed such as a null, insertion, truncations, point or promoter mutations. Recombinant DNA methods continue to improve and will inevitably serve as a foundation to approach biological and commercial problems in the foreseeable future.

Defining Statement

The primary objective of undertaking drinking water microbiology is to prevent waterborne disease. This objective can be achieved through proper assessment of source water quality, matching it against sufficient water treatment and control practices including drinking water distribution, and by monitoring their effectiveness. This article addresses characteristics of drinking water microbiota, water treatment practices in use, and monitoring and control strategies.

[☆]*Change History:* February 2015, JW Santo Domingo, N Ashbolt, and EW Rice updated abstract, introduction, new water regulations, and sections on molecular tools and drinking water emerging issues, and added new keywords and figures 2 and 3, and updated Table 3.

This article is an update of P.S. Berger, R.M. Clark, D.J. Reasoner, E.W. Rice, J.W. Santo Domingo, Water, Drinking, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 121–137.

Introduction

Safe drinking water is one of the most successful public health interventions ever developed. Ancient civilizations practiced water treatment, as evidenced by Egyptian inscriptions and Sanskrit writings. Babylonians had piped water since 4000 BC, and sand filtration was in use in some cities as early as the sixteenth century. Chlorination of drinking water, so widely used today, was not introduced until the first decade of the twentieth century. Sand filtration and chlorination practices dramatically decreased the incidence of waterborne disease, although waterborne disease is still a problem in the United States and elsewhere when systems are inappropriately managed or unusually challenged.

As with many developed regions, the United States takes a multiple-barrier approach in preventing pathogen entry into drinking water. This means that a drinking water distribution system is required to use several barriers/treatment steps to counter enteric pathogens, throughout the entire process from source water management (e.g., intake) to drinking water exposure (e.g., the tap). Systems using surface water may control human activities on the watershed supplying the system. In groundwater systems natural barriers such as soil, aquitards and bedrock function in preventing passage of pathogens into well water. As part of this approach, a system should use the cleanest source water available (including use of watershed controls), provide appropriate water treatment for the water source used, and minimize pathogen entry into the distribution system via cross-connections and back-flow, pipe breaks, and other distribution system deficiencies. In addition, the multiple-barrier approach includes a good management plan, minimum operator standards and training, a state laboratory accreditation program, periodic on-site sanitary surveys, and a host of other quality assurance programs that collectively reduce the potential for drinking water contamination. An integral part of this approach is for a system to understand the potential sources of contamination in the watershed, including human activity and livestock practices to minimize human-infectious enteric pathogens. Implementing strong plumbing system codes provides additional protection to drinking water quality.

This article discusses how water is treated and monitored to insure its microbiological safety for human consumption. The primary focus is on water treatment practices as used in developed regions like the United States. The article also includes a brief description of the drinking water regulations for microbiology in the United States and discusses emerging concerns from water-based pathogens and antibiotic-resistant genes in the environment.

Indicator Organisms in Microbial Monitoring

Drinking water can be a vector of waterborne and water-based pathogens and therefore exposure to contaminated drinking water can result in a number of illnesses such as gastroenteritis (when ingested) and respiratory diseases (when such organisms enter via the respiratory tract). Waterborne pathogens are enteric agents that pass in feces and are ingested via water, and include numerous viral, bacterial and parasitic protozoa pathogens (Ashbolt et al., 2001). Water-based pathogens are non-enteric microorganisms that spend part of their life cycle in water environments, some of which are pathogens of vulnerable groups, such as the immunocompromised and elderly. Ideally, specific detection of the various waterborne and water-based pathogens would be the most direct approach in determining their presence and the need for control. Unfortunately, in actual practice, this is impractical for several reasons. The variety of potential pathogens is so broad, that a search for all, -especially on a routine basis, would be extremely difficult, time-consuming, and expensive. Moreover, the efficiency of current techniques for recovering and detecting known drinking water pathogens is often poor, primarily due to the low levels of these organisms in drinking water. In addition, detection does not always translate into risks as some strains of the same species are more pathogenic than others, and current detection methods cannot easily discriminate between pathogenic and nonpathogenic strains.

Although culture techniques for isolating many bacterial pathogens are available, some are nonselective, thus allowing nontarget organisms to proliferate in numbers that overgrow the pathogen. Viral pathogens are fastidious in their growth requirements and grow only in special tissue cultures that are expensive and often difficult to maintain. Some viruses cannot yet be cultivated in the laboratory, such as human noroviruses. Currently, methods for pathogenic protozoa are inefficient due to the poor recovery yields of methods used for detection and the need to filter large volumes of water to detect protozoan in situ levels. Extended delays can be involved in carrying out specific identification procedures for pathogens, and only certain laboratories with specially trained technologists may have the expertise to carry out some of these procedures. Moreover, if pathogens were present in drinking water, their concentrations would usually be sufficiently low to require analysis of large-volume samples.

Because of the problems associated with trying to detect specific enteric pathogens, indicator organisms are used as fecal indicators, as treatment surrogates to assess the microbiological quality of drinking water, and to monitor the integrity of distribution systems. The ideal drinking water indicator has the following attributes.

- It is suitable for all types of drinking water.
- It is present in sewage and fecally-polluted waters at much higher densities than enteric pathogens.
- Its environmental persistence is at least that of waterborne pathogens.
- It is at least as resistant to disinfection as the hardest waterborne pathogens.
- It is easily detected by simple, inexpensive, laboratory tests in the shortest time with accurate results.
- It is stable and nonpathogenic.
- It is generally not present in waters not contaminated by feces from warm blooded animals.

The indicators generally employed worldwide are total coliforms (e.g., as a measure of disinfection efficacy), thermotolerant coliforms, and/or *Escherichia coli* (as fecal indicators). Total coliforms constitute a broad group of bacterial species, all phylogenetically affiliated to the family *Enterobacteriaceae*. They are usually not pathogenic and are widespread in ambient water, where some grow unassociated with fecal contamination. Commonly, they are more numerous than *E. coli* in sewage and animal excreta, and hence are used to provide a flag for potential fecal contamination. While total coliforms are encompassed by multiple genera with a variety of physiological traits, they are defined by their ability to produce acid and gas from lactose on selective culture media designed to recover enteric bacteria. The preferred culture media used to detect and enumerate vary by country (e.g., in the US and European countries). This bacterial group include most species of the genera *Enterobacter*, *Klebsiella*, *Citrobacter*, and *Escherichia*, although some species of *Serratia*, and other genera may also be included, depending on the medium used. Total coliforms are used to determine the effectiveness of water treatment processes, to monitor the integrity of the underground pipe network called the drinking water distribution system, and as a screening group for fresh fecal contamination. Treatment and other water system practices that provide coliform-free water should also reduce pathogens to minimal levels. However, as with *E. coli*, total coliforms are inadequate for predicting the potential presence of parasitic protozoan cysts and enteric viruses, since coliforms are more susceptible to disinfection than these other organisms. Furthermore, for microfiltration processes, bacteria and cysts maybe removed, but limited levels of the smaller enteric viruses may remain. Therefore it is important to match the appropriate treatment indicator with the class of pathogen and treatment process to be monitored.

Thermotolerant coliforms are a subset of the total coliform group, primarily including *E. coli* and a few thermotolerant strains of *Klebsiella*. Thermotolerant coliforms and *E. coli* are the preferred indicators of fresh fecal contamination, not total coliforms, as reflected in recent changes to the total coliform rule (EPA, 2009) and by WHO (2008). However, total coliforms are a more suitable indicator than thermotolerant coliforms or *E. coli* for determining the vulnerability of a distribution system to surface water contamination, especially in the absence of fecally contaminated samples at the times and locations of sample collection. Total coliforms are usually present at much higher concentrations in source waters than these other indicators, and they are relatively more resistant to chlorine and other environmental stresses. Most countries that have formal drinking water rules, including the United States, monitor for total coliforms to flag potential contamination, loss of disinfection treatment efficacy and breaches of distribution system integrity. From a regulatory perspective, *E. coli* (or enterococci and coliphages in groundwater) are used to flag fecal contamination and their presence would normally result in follow-up action to identify and manage the source of contamination.

In addition to the indicators just described, other drinking water indicators also have been used or suggested, usually as a supplement to total coliforms or *E. coli*. For example, coliphages are used as surrogates of human enteric virus behavior (particularly for groundwater sources), while spores of *Clostridium perfringens* are used as surrogates for parasitic protozoa oo/cysts removal. As with total coliforms, heterotrophic bacteria (as measured by the heterotrophic plate count [HPC] method) are used to assess treatment performance. Specific molecular methods targeting genes associated to members of the *Bacteroidales* and to *Methanobrevibacter smithii* are also used to aid in identifying the source(s) of fecal contamination. Also for source tracking several chemicals have been used, such as, fecal sterols, caffeine, and disinfectant residuals. For monitoring ambient freshwaters, the US Environmental Protection Agency (EPA) suggests the use of enterococci or *E. coli* as indicators, with enterococci providing the strongest link to health outcome for both fresh and marine waters (EPA, 2012).

EPA Drinking Water Regulations

General

The EPA publishes enforceable regulations under the Safe Drinking Water Act, which was passed by the US Congress in 1974 and subsequently amended. Regulations under this Act apply to every public water system (PWS), that is, to those systems that regularly serve 25 or more people at least 60 days out of the year, or that have 15 or more service connections. There are approximately 160000 PWSs in the United States, of which close to 15000 are surface water systems and the rest are groundwater systems. About 9000 systems serve 3300 people or more, and these 9000 systems serve a total of approximately 258 million people. Based on EPA's definition, PWSs can be classified as a Community Water System (a public water system that supplies water to the same population year-round), a Non-Transient Non-Community Water System (a public water system that regularly supplies water to at least 25 of the same people at least six months per year, but not year-round. Some examples are schools, factories, office buildings, and hospitals which have their own water systems), or a Transient Non-Community Water System (a public water system that provides water in a place such as a gas station or campground where people do not remain for long periods of time. The systems can also be classified according to the number of people they serve, that is, from very small (serving 25–500 people) to very large systems (serving >100000 people) (www.water.epa.gov/infrastructure/drinkingwater/pws/factoids.cfm).

The EPA has four classes of regulations to protect the public against waterborne pathogens: the Total Coliform Rule and followon Revised Total Coliform Rule, the Surface Water Treatment Rule and supplemental Long Term 2 Enhanced Surface Water Treatment Rule, the Groundwater Rule, and the Aircraft Drinking Water Rule. These rules are summarized here. The Code of Federal Regulations (40 CFR 141 and 142) provides detailed requirements about the existing rules. The *Federal Register* (FR) also provides detailed requirements, along with the rationale for these requirements. (The general website for the Code of Federal Regulations and the Federal Register is <http://www.gpoaccess.gov>).

Total Coliform Rule and Revised Total Coliform Rule

The Total Coliform Rule (TCR) (54 FR 27544; 29 June 1989) sets a maximum contaminant level (MCL) for total coliforms, so that only *E. coli* now has a MCL, which is 0 detects in a 100 ml sample of drinking water. Total coliforms are used in the Revised Total Coliform Rule to indicate the need for follow-up sampling and for system assessments. Provisions of the Revised Total Coliform Rule become effective April 1, 2016. If a system exceeds the MCL for repeat samples according to the conditions described in CFR 141.63 c(1) through c(4), it must notify the public using mandatory language developed by the EPA. The required monitoring frequency for a system depends on the size of the population served and whether the system operates full time or not. This frequency ranges from 480 samples per month for the largest systems to once annually for certain of the smallest systems. The regulation also requires all systems to have a written plan identifying where samples are to be collected.

If a system has a total coliform-positive sample, it must analyze for the presence of *E. coli* on three different samples (for small systems, four) within 24 h of being notified of the positive sample. In addition, systems that collect fewer than five samples per month must, with some exceptions, collect at least five routine samples the next month of operation. Both routine and repeat samples count toward calculating compliance with the MCL. If two consecutive samples at a site are total coliform-positive and one is also thermotolerant coliforms- or *E. coli*-positive, the system is in violation of the MCL and must notify the public using more urgent mandatory language than used for the presence of total coliforms alone. The TCR also requires each system that collects fewer than five samples per month to have the system inspected every 5 years (10 years for certain types of systems using only protected and disinfected groundwater). Some of the regulations implemented in the TCR will change in the forthcoming Revised Total Coliform Rule (RTCRC).

Surface Water Treatment Requirements

The Surface Water Treatment Rule (SWTR) (54 FR 27486; 29 June 1989) was designed to protect all PWSs that use surface water, or groundwater under the direct influence of surface water, against waterborne pathogens, specifically including *Giardia lamblia*, viruses, and *Legionella*. The SWTR requires systems to use sufficient water treatment (removal and/or inactivation) to reduce *G. lamblia* cysts by at least 99.9% (3 logs) and enteric viruses by at least 99.99% (4 logs). The SWTR specifies criteria for meeting these standards, and criteria for avoiding filtration. More specifically, the SWTR requires all systems covered by the rule to disinfect. It also requires all such systems to filter their water, unless (1) the system has an effective watershed control program; (2) it complies with the TCR and MCL for trihalomethanes; (3) it uses a good-quality source water, as defined as having no more than 20 thermotolerant coliforms per 100 ml or no more than 100 total coliforms per 100 ml, and a turbidity (opaqueness) no greater than 5 nephelometric turbidity units (NTU), and (4) it meets stringent disinfection conditions.

The regulation and associated EPA guidance assist the system in meeting the specified pathogen reduction levels by identifying pertinent CT values for disinfection inactivation (*C*, disinfectant concentration in mg l⁻¹; *T*, time of disinfectant contact with the water in min). CT values are provided for *Giardia* and enteric viruses by disinfectant type (e.g., chlorine, chloramines, ozone, or chlorine dioxide), water pH, and temperature. The regulation also requires a system using surface water to have a 0.2 mg l⁻¹ disinfectant residual continually entering the distribution system and at least a detectable disinfectant residual in at least 95% of the sample sites throughout the distribution system. The rule specifies the monitoring frequency and locations for determining these disinfection residuals and (for unfiltered systems) testing source water quality.

The SWTR has been strengthened by three subsequent rules, the Interim Enhanced SWTR (63 FR 69478, 16 December 1998), Long-Term 1 Enhanced SWTR (67 FR 1812; 14 January 2002), and Long-Term 2 Enhanced SWTR (LT2ESWTR) (71 FR 6135; 5 January 2006). These three rules collectively tighten the turbidity standards, require systems to monitor the turbidity levels leaving each individual filter, require periodic on-site sanitary surveys by the state or primary authority, require additional treatment for systems with elevated source water *Cryptosporidium* concentrations, and require the system either to cover all finished drinking water storage facilities (e.g., reservoirs) or treat the water in those facilities, as well as other new requirements. The primary purpose of these new requirements is to control *Cryptosporidium* oocysts. Another purpose is to ensure that utilities do not degrade pathogen control while complying with other regulations that control for disinfection by-products (formed by the reaction of disinfectants with organic material in the source water). Under these three SWTRs, a system must provide sufficient water treatment to reduce *Cryptosporidium* by at least 99% (2 logs). However, because of a concern that systems drawing water from a poor-quality source might be exposing the public to a greater pathogen risk than is reasonable, the LT2ESWTR requires systems to provide additional *Cryptosporidium* treatment if required source water monitoring (initially screened by *E. coli* levels for small systems) indicates the average density of *Cryptosporidium* oocysts is 0.075 l⁻¹ or greater (for unfiltered systems, > 0.01 l⁻¹). The actual required minimum level of additional treatment depends upon how much greater than 0.075 l⁻¹ is the average *Cryptosporidium* density. In this manner, in theory, the consumer would have approximately the same risk of infection, regardless of the system used.

Groundwater Rule

The Groundwater Rule (GWR) (71 FR 65574; 8 November 2006) applies to all PWSs that use groundwater (about 142000 systems). However, systems that use groundwater that are under the direct influence of surface water must instead comply with the SWTR. Under the GWR, the state will determine whether a system is fecally contaminated or is vulnerable to fecal contamination. This determination may be made by a variety of means, including direct monitoring of the source water (usually the well), periodic

on-site sanitary surveys by a trained inspector, and an examination of the site's hydrology. A fecally-contaminated site is required to take corrective action such as providing an alternate water source, eliminating the contamination source, correcting all significant deficiencies found during a sanitary survey, and/or providing treatment (removal, inactivation, or both) that reliably achieves at least a 4-log (99.99%) virus reduction. Under the rule, a system may use *E. coli*, enterococci, or coliphage for source water monitoring; the rule approves specific analytical methods for these three indicators. The rule specifies when, where, and how often a system must be monitored; the frequency of required on-site sanitary surveys, minimum disinfectant requirements, and other provisions.

Aircraft Drinking Water Rule

The Aircraft Drinking Water Rule (74 FR 53590; October 19, 2009) applies to aircraft PWSs. It applies to scheduled and non-scheduled charter air transportation. Airlines which do not regularly serve water to passengers, or serve at least 25 passengers for at least 60 days per year are exempt from this regulation. Sampling should be at least one sample from a galley and one from a lavatory for total coliform and disinfectant residual. For airlines of >20 aircraft, 25% of the fleet should be sampled quarterly, and for airlines of <20 aircraft, all should be sampled quarterly. Each aircraft should have its water system disinfected and flushed no less than quarterly and watering points (trucks, carts, hoses etc.). Coliform sampling is required once per year for aircraft that are flushed and disinfected quarterly, once per six months for aircraft that are flushed and disinfected one to three times per year, once per quarter for aircraft that are flushed and disinfected twice per year, and monthly for aircraft that are flushed and disinfected once per year or less. The sample volume for coliform testing is 100 ml. A total coliform sample should be followed up by *E. coli* testing. Four repeat samples are required for a total coliform and *E. coli* positive samples. In the event of a positive *E. coli* sample, public access to the water should be restricted, and the system should be disinfected and flushed. If a sample is total coliform positive only, corrective actions should be taken until repeat samples are total coliform negative.

Other US Rules

EPA has published a list of pathogens and chemical contaminants that are not specifically regulated but occur, or are likely to occur, in water systems, pose a potential health risk, and may need to be regulated (63 FR 10274; 2 March 1998). The Contaminant Candidate List (CCL), most recently published as CCL-3 in 2012 includes adenoviruses, caliciviruses, *Campylobacter jejuni*, enteroviruses, *E. coli* O157, *Helicobacter pylori*, hepatitis A virus, *Legionella pneumophila*, *Mycobacterium avium* complex, *Naegleria fowleri*, *Salmonella enterica*, and *Shigella sonnei*. The EPA is conducting research on each of these pathogens to determine whether new regulations are needed to control them. Some of these organisms are opportunistic pathogens; hence the EPA is required to pay special attention to consumers at higher risk (i.e., immunocompromised).

In developing future regulations, EPA will assess the risk of waterborne and water-based pathogens (i.e. *L. pneumophila* & non-tuberculous mycobacteria). This assessment will be facilitated by the development of risk models that would specify, for example, the level of pathogen inactivation/removal needed by a ground or surface water system and, thus, whether that system would need further monitoring or other requirements such as disinfection. A satisfactory assessment of risk depends on the evaluation of a number of factors, including infectious dose, virulence, ratio of infection to disease, identification of susceptible groups, the extent to which a pathogen is likely to be present in drinking water and the percentage that are viable. Despite the development and evaluation of microbial risk assessment and modeling tools for water-associated pathogens, this approach has not been widely adopted.

Rules and Guidelines of Other Countries

Several multi-country organizations have strong drinking water directives or guidance. These include the World Health Organization (WHO) and the European Union (EU). WHO's *Guidelines for Drinking-water Quality*, third edition (2006), contains a comprehensive strategy for ensuring safe drinking water, from the water source through treatment and distribution to the consumer – in what it calls a Water Safety Plan that is risk-based management and follows the hazard analysis critical control point (HACCP) approach used in the food industry. The guidelines do not set specific numerical goals for removal/inactivation of pathogens or indicators of water quality. Rather WHO takes the position that a community should set its health-based goal, such as one Disability Adjusted Life Year (DALY) per million people in a year, then based on reference pathogens (addressing relevant viral, bacterial and parasitic protozoa) determine overall log reductions to stay below the risk-based targets for each pathogen group. Therefore, there is no single list of drinking water standards, but individual regions set these according to local needs and capacities. Guidelines are provided for a large variety of drinking water systems and circumstances, including large metropolitan systems, small community piped systems, non-piped systems in communities and in individual dwellings, large buildings, food production, emergencies and disasters, and travelers and commercial transport. The document describes the approaches used in deriving the guidelines, including guideline values, and includes fact sheets on significant microbial and chemical hazards.

A key component of the WHO guidelines is the Water Safety Plan (WSP). The WSP has several elements, for example, the development of an individual water safety plan that includes an assessment of risk from source to tap; the identification of control measures and, for each measure, appropriate monitoring that, collectively, will control the identified risks in a timely manner; and

the development of management plans describing actions to be taken during normal operation or incident conditions, as well as supporting programs (<http://www.who.int>).

EU directive 98/83/EC (3 November 1998) specifies that no *E. coli*, enterococci, or coliform bacteria should be detected in 100 ml of drinking water. It also states that no abnormal change in heterotrophic colony counts (22 °C) should occur. The directive also specifies that if water originates from or is influenced by surface water, it must also monitor *C. perfringens* (including spores). If the density of *C. perfringens* exceeds 1/100 ml, the utility must investigate to ensure that water has not been contaminated by enteric pathogens. In contrast to US standards, the monitoring frequency for bacterial indicators is based upon the volume of water produced or distributed each day, rather than by the number of people served by the utility (<http://europa.eu>). Among individual countries with an effective drinking water management plan approach are Canada (<http://www.hc-sc.gc.ca>), Australia (<http://www.waterquality.crc.org.au>), and New Zealand (<http://www.mfe.govt.nz>). These countries focus more on the whole of system HACCP approach, knowing that to provide water at an annual risk threshold below one infection per 10000 people or <1 disability adjusted life year (DALY) per million it is not feasible to monitor at the drinking water product end alone. For example, drinking water would need to be sampled every 15 min to be sure 95% of the time to have <1 virus/10⁶ l, the risk-based target to achieve <1 infection per 10000 people (Smeets et al., 2010). Hence, there is a need to provide validation of likely human-infectious pathogen numbers upstream and relevant surrogates of treatment removal to estimate these risk-based targets.

Sources, Treatment, and Distribution

Sources of Water Supply

Drinking water sources can be divided into two categories: surface water and groundwaters; treatment requirements vary with the source. Microbiologically, groundwaters tend to be of better quality than surface water sources and, consequently, require less intensive treatment. Most groundwaters supplies used for drinking water are pumped wells (dug, drilled, or driven), artesian wells, or springs.

Surface water sources include streams, rivers, ponds, lakes, and manmade impoundments and reservoirs. These sources include precipitation and runoff that is not lost to the atmosphere by evaporation and does not enter the ground via infiltration and percolation. Surface waters become contaminated by human pathogens through direct and indirect inputs of municipal sewage and other sources of human and animal excreta. Removal or inactivation of these microorganisms to provide safe drinking water involves a multiple-barrier concept, using a variety of treatment processes, in addition to measures aimed at controlling or reducing source water pollution (source protection).

Bacterial concentrations in groundwater, as measured by the HPC, are only a very small fraction of the total active cells and often <100 colony-forming units (CFU) ml⁻¹; coliforms are normally absent in that volume. Bacterial concentrations in surface waters depend on the degree of contamination with human and animal fecal material. Pristine and relatively uncontaminated surface waters commonly contain total coliform bacteria that range from <1/100 to >10⁶/100 ml, and thermotolerant coliforms/*E. coli* range from <1/100 to >10⁵/100 ml. Raw water containing more than 2000 thermotolerant coliforms/100 ml should not be used as a drinking water source unless there is considerable pre-treatment, such as by slow deep-sand filtration or riverbank infiltration.

Water Treatment

The major water treatment processes for improving the microbiological quality of surface waters for human consumption include coagulation and flocculation, sedimentation, filtration, and disinfection. Most groundwater used as drinking water sources are only disinfected, if they are treated at all, hence the importance to identify the likelihood of surface water intrusion for groundwater systems. Figure 1 is a schematic of the unit processes in a conventional drinking water treatment system used for surface waters. Several additional treatment processes are widely used, for example, softening, fluoridation, and iron removal, but these are for aesthetic or non-microbiological reasons and not discussed here.

Another process called 'bank filtration' is used in various countries (e.g., Finland, Germany and the Netherlands) as a replacement for coagulation/flocculation and filtration treatment steps to provide water for drinking water supply purposes. Bank filtration wells are installed adjacent to a river or other source of water. The wells capture ground water from the landward side and surface water that is induced by well pumping to infiltrate through the subsurface and into the well. The produced water is processed through other treatment steps for drinking water. The use of 'bank filtration' in the United States has seen limited application.

Coagulation, flocculation, and sedimentation

In the first step, raw water is pumped into a rapid mix unit, where chemical coagulants are added to destabilize particles in the water electrostatically (i.e., make them 'sticky'). This step is referred to as coagulation. Then water enters a flocculation basin, which is often a series of chambers with slow moving paddles. During flocculation, the destabilized particles are brought into contact with each other so they aggregate into larger particles, or flocs. During this process microorganisms become trapped by, or attached to, the flocs. The optimal coagulation practice varies with water pH and temperature, raw water turbidity, and type of coagulant(s) used. Commonly used coagulants include aluminum sulfate (alum), calcium oxide (lime), ferrous sulfate, and ferric

Figure 1 Conventional filtration system for drinking water treatment.

chloride. Often, coagulant aids such as activated silica, bentonite clay, and polyelectrolytes (synthetic polymers of varying charge) are also used to reduce the concentration of primary coagulants employed.

After flocculation, water enters the sedimentation basin(s), where flocs are given time to settle by gravity. Some systems omit this step and feed the flocculated water directly to filters (direct filtration). If the source waters are highly turbid, systems may include an additional sedimentation step prior to coagulation (presedimentation). Sludge in the sedimentation basins is removed and discharged to a municipal sewer, lagooned, or dewatered and hauled to a landfill. The sedimentation basins are generally equipped with sludge removal mechanisms; if not, they usually have a sloping bottom so that most of the sludge flows out with the water when the basin is drained for cleaning.

Filtration

The next treatment step is filtration, which removes suspended and colloidal material that has not settled. The filtration unit consists of steel or concrete vessels containing granular materials such as graded sand, anthracite, and/or gravel. Three types of filters are commonly used: rapid granular filters, slow sand filters, and diatomaceous earth (DE) filters.

Rapid granular filters

The most commonly used filter in the United States is the rapid granular filter. These filters may consist of silica sand, anthracite coal, and/or other materials. Filters are usually set up to provide gradation in filter media, with the coarsest particles on top and the smallest on the bottom. In a rapid granular filter, the rate at which water is applied is at least 2 gal min^{-1} per square foot of surface area.

Rapid granular filters gradually accumulate a large amount of particles that impede water flow; thus, the filters must be periodically cleaned. In this process, water flow through the filter is reversed in a process termed 'backwashing.' Backwashing expands the filter media, thereby releasing trapped particles into the water. Jets of water, air injection, or mechanical agitation at the surface may improve the process. The filter back-wash water should be disposed of in an environmentally acceptable manner.

Slow sand filters

Slow sand filters are similar to the rapid granular filters, except that water flows through the filter at a much slower rate, $0.05\text{--}0.15 \text{ gal min}^{-1}$ per square foot of surface area, and pretreatment (coagulation, flocculation, and sedimentation) is often omitted. Removal occurs primarily in the upper portion of the sand, by straining, sedimentation, adsorption, and chemical and microbiological action. As contaminants are removed, a layer of deposited material called a 'schmutzdecke' forms. Schmutzdecke contains a large number of bacteria and associated extracellular matrix (biofilm) that break down organic material in the water and acts as an excellent microbial pathogen trap. However, periodically the schmutzdecke clogs the filter, and thus it must be removed by scraping

off the top layer of sand so as to restore sufficient water flow through the sand filter. Normally, slow sand filters are used by systems with relatively clean source water (turbidity of 10 NTU or less and no undesirable chemical contaminants). They require far less maintenance than rapid granular filters, but must be much larger in surface area to produce a given volume of drinking water.

Diatomaceous earth (DE) filtration

In DE filtration, solids are removed by passing water through a thin filter consisting of a layer of DE supported on a rigid base (septum). DE is composed of crushed siliceous shells of diatoms (microscopic algae). To maintain adequate water flow, additional DE called body feed is continually added to the raw water during operation. Like slow sand filters, systems that use DE are usually small with relatively clean source water, and often pretreatment is omitted.

Granular activated carbon (GAC) filters

GAC filters are sometimes used in conjunction with rapid granular filters to control taste and odor problems as well as to remove cyanobacterial toxins and other undesirable chemical contaminants. In Europe, many systems treat the water with ozone (ozonation) before applying it to the GAC filters. Ozonation not only disinfects the water but partly degrades organic contaminants so they are more readily utilized by heterotrophic bacteria in the filter. The high density of bacteria that grow on the surface of the filter media significantly reduces the level of organic substances in the water as it passes through the filter. However, where there is biofilm growth, there are also amoebae and other protozoa/metazoan feeding on bacterial cells. Some of these protozoa may host the amplification of water-based pathogens, such as *Legionella* that may then seed the downstream drinking water distribution system.

Membrane processes

Membrane technology has become increasingly popular in potable water treatment. It has been used for desalination, removal of dissolved inorganic chemicals and various pesticides, water softening, and removal of solids. The simplest way to describe membrane technology is that water is forced through a porous membrane under pressure while suspended solids, larger molecules, or ions are held back or rejected by the membrane.

Membrane processes may be pressure- or electricity-driven. The pressure-driven processes are microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). During MF water is forced through a porous membrane with nominal pore sizes of 0.2–45 μm , which is relatively large compared with other membrane processes. Hence, MF is suitable for the removal of small particles, including bacteria and protozoa. For UF a membrane with a pore size less than 0.1 μm is used to remove colloids, and when used with <60 k Dalton molecular weight cut-off (MWCO) membrane viruses and high-molecular-weight organic compounds are removed. Indeed, UF is a good way to sample and concentrate enteric viruses from water for further testing. MF or UF will not remove dissolved organic and/or inorganic species without advanced pretreatment to transform the dissolved species into particulate form. NF treatment rejects even smaller molecules than UF, and has been used for water softening and removal of total dissolved solids and viruses. RO systems have the highest rejection rate of all of the membrane processes. It has been used primarily for desalination of seawater. The electricity driven processes are electrodialysis and electrodialysis reversal. Electrodialysis (ED) transfers ions through a membrane as a result of direct electric current, and ED reversal is similar to ED except that the polarity of the direct current process is periodically reversed. These types of systems are used primarily for the treatment of brackish water. Of these processes, NF seems to have the greatest potential for increased use in water treatment.

Disinfection

Disinfection is the primary means for inactivating pathogenic microorganisms in water. It should be noted that disinfection treatments do not sterilize water as viable non-pathogenic bacteria and other microorganisms may still be present. Also, depending on the disinfectant used, some pathogens may persist. For systems using groundwater, disinfection is generally the only treatment practiced. Several disinfectants are available, including chlorine, chloramines (chlorine combined with ammonia or organic amines), ozone, chlorine dioxide, and ultraviolet light. All are oxidizing agents.

Chlorination is, by far, the most common disinfection technique practiced in the United States. The dose of chlorine usually applied is sufficiently high to meet chlorine demand (i.e., the tendency of organic substances and ammonia to react with chlorine) and still leave a sufficient concentration (chlorine residual) to inactivate microorganisms throughout the distribution system. A major shortcoming is that chlorine combines with organic substances in the water to produce disinfection by-products (DBP), some of which are toxic (e.g., trihalomethanes such as chloroform). Unlike chlorine, monochloramine (NH_2Cl) (the only effective chloramine disinfectant) does not result in any known significant trihalomethane formation, but may produce low levels of other more toxic DBPs, such as nitrosamines. The microbial inactivation rates of monochloramine are substantially less than that of chlorine. Chlorine dioxide produces few DBP, but its intermediates (chlorite and chlorate) are toxic. Like chlorine, monochloramine and chlorine dioxide are useful because they provide disinfectant residuals in the water throughout the distribution system.

Ozone is the most effective disinfectant generally available, and is widely used in water treatment in Europe. Fewer toxic by-products have been identified for ozone than for chlorine, but ozone is more expensive and does not leave a significant residual for distribution systems. There is increased interest in the United States in using ozone as a pre-disinfectant, followed by chlorine or monochloramine. This combined approach would allow a system to control the formation of toxic by-products, yet maintain a disinfectant residual in the distribution system.

Mostly used by smaller systems and individual domestic systems (especially those using groundwater), ultraviolet light is also being considered by some larger drinking water treatment facilities to comply with the LT2ESWTR. The optimum wavelength for biocidal effectiveness is 254 nm. Dosage is expressed as the product of radiation intensity (mJ) and the time (s) per unit area (cm²). Ultraviolet light does not produce disinfectant by-products in water and leaves no disinfectant residual. Its effectiveness is reduced by high turbidity, air bubbles, some dissolved chemicals that absorb UV, the lack of reliable methods or meters to measure dosage, and equipment maintenance and reliability considerations.

It has been demonstrated that UV irradiation is very effective against (oo)cysts of *Cryptosporidium* and *Giardia*. These two pathogenic organisms are of major importance for the safety of drinking water as they exhibit more resistance to chlorination. Results of inactivation studies have shown that UV is effective against all waterborne pathogens; however enteric viruses, specifically adenoviruses, and bacterial spores show some resistance to 254 nm UV inactivation and so-called medium pressure, polychromatic UV treatment is more effective against these microorganisms.

Microbiology of Treatment Processes

The removal of microorganisms by the treatment processes through the filtration step is variable due to a variety of factors, including fluctuating source water quality, coagulant dose, pH, water temperature, depth of filter, filter medium particle size, and filtration rate. Drinking water treatment processes and the approximate percentage removal/inactivation of microorganisms achieved by each of the processes are shown in Table 1. Removal percentages represent only removal percentages for that stage, not the cumulative percentage. It is difficult to establish the cumulative removal percentages from one step to the next because they vary depending on what treatments are used and due to the considerable variation in the data reported from different studies. These differences reflect different source waters and qualities, different treatment processes, and different operating conditions. Thus, direct comparison of study results is difficult, but sufficient studies have been conducted to permit general characterization of the effectiveness of water treatment processes for removing microorganisms.

Slow sand filters

The efficiency of microorganism removal by slow sand filters is influenced by several factors, including the particle size of the filter medium and the extent to which the schmutzdecke has developed. A filter with a smaller particle size is more efficient in microbe removal, but results in shortened filter runs, that is, more frequent filter cleaning is necessary to maintain a suitable water flow rate. In addition, new or newly cleaned slow sand filters require some conditioning (ripening) before they are effective in removing microorganisms. The ripening period allows a biologically active schmutzdecke to build up on the particles and in the filter bed. This layer then assists in the filtration of other particles and colloids from the water. The schmutzdecke is important in microbe removal, particularly for bacteria and viruses. Virus removal by sterile sand is negligible, and removal by clean nonsterile sand is variable but poor.

Removal of coliform bacteria by slow sand filters ranges from about 83% with new filter sand to nearly 100% for sand with an established schmutzdecke. Removal of poliovirus type 1 by slow sand filters ranges from 22% to 96% for clean sand to >99.9% for

Table 1 Microorganism removal efficiency (%)^a

^dWith pretreatment and precoating of filter.

sand with an established biological population. Removal of *Giardia* cysts (protozoan) by slow sand filtration ranges from 59% to 99.98%.

Cold water temperatures normally decrease microorganism removals by slow sand filtration. At water temperatures $<5^{\circ}\text{C}$, removal of heterotrophic bacteria (measured by HPC) and coliforms decreases by about 2 and 2–10%, respectively, compared with removals at temperatures greater than 15°C . Virus removals decrease by about 0.5% and protozoan cyst removals decline by 0–6.2%. Increased water flow through the filter (filtration rate) also results in decreased microorganism removals.

Rapid granular filters

Systems that use rapid granular filtration must first pretreat the raw source water (coagulation, flocculation, and sedimentation) for effective microbial removal, unless the water is clear (turbidity <10 NTU). Effective pretreatment should reduce the turbidity of muddy surface water to a level well below 1 NTU. Effective pretreatment and filtration collectively should reduce the turbidity to 0.1 NTU or less.

Microorganism removals achieved by pretreatment and rapid granular filtration are high. Bacterial removals (heterotrophic bacteria and coliforms) range from 86% to 98.8%, and virus removals range from 90% to $>99.99\%$. The coagulation and filtration processes generally can achieve removals of protozoan cysts ranging from 83% to 99.99%. Efficient removal of *Giardia* and other protozoan cysts by filtration is dependent on an adequate coagulant dose. A change in alum dose from 5 to 10 mg l^{-1} can increase the removal of *Giardia* cysts from 96% to $>99\%$.

Factors that adversely affect removal efficiency include interruption of chemical feed (coagulants and polymers), poor filter efficiency at the beginning of a filter run, sudden increases in water flow, and turbidity breakthrough that can occur with higher filter head loss (resistance to water passage through the filter) at the end of a filter run. Any of these factors can seriously degrade the microbiological quality of the filtered water. In addition, some source waters are so highly polluted that full treatment (pretreatment, filtration, and disinfection) may not achieve a suitable level of microbiological reduction.

Diatomaceous earth

Bacterial removals by DE filtration are affected by the grade of DE used. When fine DE is used that yields a median pore size of 1.5 mm in the filter cake, bacterial removals of nearly 100% can be achieved. Lower percentage removals occur when coarser DE is used that provides increased median pore size. However, by chemical conditioning of coarser grades of DE, good bacterial removals can be obtained.

DE filtration can satisfactorily remove viruses from water, but to be most effective, the raw water must be pretreated with a coagulant aid (polymer) or the DE filter cake must be chemically conditioned to enhance virus attachment to the filter material during filtration. Overall, DE filtration is most effective for removal of microorganisms in the size range of *Giardia* or *Entamoeba histolytica* cysts. *Giardia* cyst removals of 99% or greater can be achieved by proper DE filter operation. The use of DE to remove smaller organisms (bacteria and viruses) can be improved by coating it with aluminum hydroxide precipitate. This coating gives the DE a positive surface electrical charge. Bacteria and viruses with a negative electrical charge are then removed by surface attachment.

Membranes

Membrane processes can be effective at removing various microbial contaminants. For example, MF and UF are generally capable of removing 6–7 logs of protozoan cysts and greater than 5.5 logs of bacteria. Lower removal rates are achieved for viruses: less than 2.5 logs removal.

Disinfection

General considerations

The final treatment process for drinking water to address microbial contamination is chemical or physical disinfection intended to inactivate pathogens that enter the distribution system. The effectiveness of disinfection is a function of the types of organisms to be inactivated, the quality of the water, the type and concentration of the disinfectant, the exposure or contact time, and the temperature of the water.

As stated previously, *CT* values are used to identify the level of inactivation provided by a given disinfectant for an organism under a specific environmental condition. These values are useful for comparing biocidal efficiency. Table 2 provides *CT* values for several microorganisms. Most of the available *CT* data for microorganisms of health concern were developed from laboratory studies that might not be indicative of actual *CT* values achieved in operating water treatment plants.

Water temperature can affect disinfection rates (and thus *CT* values). Microorganism inactivation rates decrease as water temperature decreases. Water pH can also affect disinfection rates. In most water systems, the pH is kept in the range of 7–9. Water pH, for example, determines the proportions of the most important chlorine species, hypo-chlorous acid (HOCl) and hypochlorite (OCl^-). Lower pH values (pH 6–7) result in the formation of HOCl, which is favorable for rapid inactivation, whereas higher pH values (pH 8–10) result in formation of OCl^- , which results in slower inactivation. For chlorine dioxide (ClO_2), which does not dissociate, inactivation is more rapid at higher pH values (pH 9) than at lower pH values (pH 7). Ozone disinfection efficacy does not appear to be affected by pH.

An important factor in bacterial inactivation is the phenomenon of cell injury. Disinfection and other environmental stresses may cause nonlethal physiological injury to waterborne bacteria. This phenomenon causes problems for monitoring water quality and calculating *CT* values, because injured bacteria may not grow on selective media normally used to detect or enumerate the

Table 2 CT value ranges for inactivation of microorganism by disinfectants

Microorganism	Free chlorine (pH 6–7)	Preformed chloramine (pH 8–9)	Chlorine dioxide (pH 6–7)	Ozone (pH 6–7)
<i>E. coli</i>	0.034–0.05	95–180	0.4–0.75	0.02
Poliovirus-1	1.1–2.5	768–3740	0.2–6.7	0.1–0.2
Rotavirus	0.01–0.05	3806–6476	0.2–2.1	0.006–0.06
Phage f2	0.08–0.18	ND	ND	ND
<i>G. lamblia</i> cysts	47–>150	2200 ^a	26 ^a	0.5–0.6
<i>G. muris</i> cysts	30–630	1400	7.2–18.5	1.8–2.0
<i>Cryptosporidium parvum</i>	7200 ^b	7200 ^c	78 ^c	5–10 ^b

ND – No data.

All CT values are for 99% inactivation at 5 °C except where noted.

^aValues for 99.9% inactivation at pH 6–9.

^b99% inactivation at pH 7 and 25 °C.

^c90% inactivation at pH 7 and 25 °C.

bacteria. Thus, the actual number of viable cells may be underestimated. In some cases, injured pathogens remain infective. Problems with detecting injured cells can be mitigated by the use of media and procedures that remain selective, yet permit the injured cells to repair metabolic damage.

Microorganism inactivation

Table 2 shows the effect of disinfectant concentration, contact time, pH, and temperature on microbial inactivation.

Chlorine Table 2 shows that enteric viruses (represented by poliovirus type 1) are more resistant to inactivation by chlorine than are bacteria (represented by *E. coli*), and protozoan cysts are nearly two orders of magnitude more resistant than the enteric viruses. *Cryptosporidium* oocysts are virtually unaffected.

Monochloramine Comparison of monochloramine with chlorine for disinfection of microorganisms (Table 2) shows that, in general, for all types of microorganisms, CT values for monochloramine are higher than CT values for free chlorine species.

Chlorine dioxide Chlorine dioxide CT values in Table 2 show that at pH 7.0, ClO₂ is not as strong a biocide as HOCl. However, as the pH is increased, the efficiency of ClO₂ for inactivation of viruses increases.

Ozone Overall, comparison of CT values for ozone with those for chlorine and ClO₂ indicates that ozone is a much more effective biocide than the other disinfectants. *E. coli* is about tenfold (1 log₁₀) more sensitive to ozone (Table 2) than poliovirus type 1. *Giardia muris* cysts are about tenfold more resistant to ozone than poliovirus type 1. Since ozone is a powerful oxidant, it reacts rapidly with both microorganisms and organic solutes and is very useful as a primary disinfectant.

The order of microbial disinfectant efficiency is O₃ > ClO₂ > HOCl > OCl[−] > NH₂Cl > NHCl₂ > RNHCl (organic chloramines). However, for technical reasons, practical handling considerations, cost and effectiveness, the frequency of use of disinfectants by utilities in the United States is generally chlorine > chloramines > O₃ > ClO₂.

Ultraviolet Light Sensitivity of the various microbial groups to ultraviolet light is similar to that for chemical disinfectants. For example, enteric bacteria are known to be more sensitive than enteric viruses and protozoan cysts. Organisms that are sub-lethally injured by UV light exposure may, under appropriate conditions, be able to repair the damage (i.e., photoreactivation or dark repair). Ranges of UV doses required for 99.9% inactivation of microorganisms of concern in drinking water are: bacteria, 7–167 mJ cm^{−2}; viruses, 16–167 mJ cm^{−2}; protozoan oo(cysts), 11–119 mJ cm^{−2}.

Distribution Systems

Description

Water transmission and distribution systems are needed to deliver water to the consumers. In 2006, the US National Academy of Sciences published a report, “Drinking Water Distribution Systems: Assessing and Reducing Risks” that recommended the following measures to control waterborne pathogens entering the distribution system.

1. Storage facilities should be inspected on a regular basis.
2. Better sanitary practices are needed during installation, repair, replacement, and rehabilitation of distribution system infrastructure.
3. Water residence times in pipes, storage facilities, and premise plumbing should be minimized.
4. Positive water pressure should be maintained.
5. Distribution system monitoring and modeling are critical to maintaining hydraulic integrity.
6. Microbial growth and biofilm development in distribution systems should be minimized.
7. Residual disinfectant choices should be balanced to meet the overall goal of protecting public health.
8. Standards for materials used in distribution systems should be updated to address their impact on water quality, and research is needed to develop new materials that will have minimal impacts.

9. Although it is difficult and costly to perform, condition assessment of buried infrastructure should be a top priority for utilities.
10. Cross-connection control should be in place for all water utilities.
11. Where feasible, surge protection devices should be installed.
12. Prior to distribution, the quality of treated water should be adjusted to minimize deterioration of water quality.

Distribution systems represent the major investment of a municipal water works and consist of large mains that carry water from the source or treatment plant, service lines that carry water from the mains to the buildings or properties being served, and storage reservoirs that provide water storage to meet demand fluctuations, for firefighting use, and to stabilize water pressure. The branch and loop (or grid) are the two basic configurations for most water distribution systems.

The layout of a branch system is similar to that of a tree branch, with smaller pipes branching off from larger pipes throughout the area served. This system, or a derivative of it, is normally used to supply rural areas where water demand is relatively low and long distances must be covered. Disadvantages of this configuration are the possibility that a large number of customers will be without service should a main break occur, and the potential water quality problems in parts of the system resulting from the presence of stagnant water. System flushing should be accomplished at regular intervals to reduce the possibility of water quality problems.

The loop configuration currently is the most widely used distribution system design. Good design practices for smaller systems call for feeder mains to form a loop approximately 1 mi (1600 m) in radius around the center of the town with additional feeder loops according to the particular layout and geography of the area to be served. The area inside and immediately surrounding the feeder loops should be gridded with connecting water mains on every street.

The most commonly used pipes for water mains are ductile iron, pre-stressed concrete cylinders, polyvinyl chloride (PVC), reinforced plastic, steel, and asbestos cement.

Microbiology

Microbiologically, water distribution systems are interesting microbial ecosystems that present a real challenge to the water utilities in terms of maintaining good-quality water with low microbial densities. The construction characteristics, operation, and maintenance of a water distribution system provide ample opportunities for microbial recontamination of the treated water during distribution. Pipe joints, valves, elbows, tees, and other fittings as well as the vast amount of pipe surface provide both changing water movement and stagnant areas where bacteria can attach and colonize. Water distribution systems are susceptible to intrusion, backflows and mains repairs that may allow entry of pathogens into the system. A cross-connection is any direct or indirect connection between the drinking water distribution system and any non-potable fluid or substance, when the water mains pressure is reduced by back siphoning or back pressure.

Biofilms in water distribution systems

Microbes found in water distribution systems can be classified into indigenous (autochthonous) and exogenous (allochthonous) populations. The indigenous organisms are well-adapted biofilm-forming bacteria that represent a stable ecosystem that is difficult to eradicate. The exogenous bacteria are contaminants that are transported into the system by a variety of mechanisms.

The development of a permanent biofilm in the distribution system occurs because several microbial groups find physical and chemical conditions conducive to colonization and growth at the solid surface/water interface. These conditions include an ample supply of nutrients (such as measured by assimilable organic carbon, AOC) for growth, a relatively stable temperature, and some degree of protection from exposure to harmful chemicals such as water disinfectant(s).

When an adequate disinfectant residual is maintained throughout the distribution system, microbial growth is usually well controlled and the density of bacteria in the bulk water traveling through the pipes will remain low – in the range of <10 to several hundred CFU ml^{-1} (HPC). The density of bacteria in the biofilm, however, may be several orders of magnitude higher, ranging upward of 1×10^5 CFU cm^{-2} (HPC). The disinfectant residual concentration needed to control the growth of the bacteria varies from one water system to another.

The choice of the medium and method used to determine the bacterial density may result in low or high counts of heterotrophic bacteria. In general, rich culture media and incubation at 35°C will yield lower counts than dilute nutrient media and incubation at $20\text{--}28^\circ\text{C}$. Factors that appear to be critical are pH, temperature, dissolved organic carbon (DOC) concentration, AOC concentration, and type of disinfectant used. The disinfectant residual will also reduce or suppress extensive biofilm growth if the residual is maintained throughout the system. Nonetheless, only a small fraction of bacteria are culturable. Methods that measure adenosine triphosphate (ATP) can provide an idea of the total viable microbial biomass in a drinking water sample. Recently, RNA-based methods have been developed to measure and identify the active bacteria present in drinking water.

Disinfectant residuals should be at least 0.2 mg l^{-1} for chlorine and 0.4 mg l^{-1} for monochloramine (NH_2Cl). Higher concentrations of disinfectant residual may be applied and maintained, but if the water contains high levels of DOC, it may be difficult to maintain an adequate disinfectant residual to control bacterial growth and still have water that is aesthetically acceptable to the consumers. Bacterial concentrations in distribution water vary from <1 CFU ml^{-1} in the water leaving the treatment plant to as high as $10^5\text{--}10^6$ CFU ml^{-1} in water from slow flow or stagnant areas of the distribution system. The concentrations of bacteria in the water and on the pipe surfaces vary spatially and temporally in the distribution system. Bacterial densities in the pipe wall biofilm and in sediments may reach 10^7 CFU cm^{-2} . The biofilm contributes bacteria to the flowing water through shear loss (erosion) and by migration of actively motile bacterial cells into the water.

Some of the bacteria commonly found in drinking water, sediments, and biofilms are listed in Table 3. Many of these bacteria are found in both the water and the biofilm, indicating the influence of the biofilm on the bacterial quality of distribution system water. Indeed, biofilms are where the most significant bacterial growth occurs in the distribution system. Moreover, such multispecies biofilms form relatively protected microniches where pathogens can seek refuge. Bacteria in drinking water are detected and enumerated using traditional culture media and methods (coliforms, thermotolerant coliforms, heterotrophic plate count, and so on). The recent development of culture-independent molecular methods (DNA- and RNA-based) has begun to reveal the great diversity of bacteria in water, biofilms, and sediments. Genes of many bacteria that cannot yet be cultured have been detected using the DNA- and RNA-based methods.

Iron and sulfur bacteria are 'nuisance' organisms that cause taste and odor problems and are often associated with groundwater sources. Nitrifying bacteria and fungi cause problems in chloraminated drinking water systems, including depletion of total chlorine residual, conversion of reduced nitrogen compounds such as ammonia to nitrite and nitrate, and high levels of heterotrophic bacteria. Invertebrates and protozoa are nuisance organisms associated with aesthetic complaints about water quality. Invertebrates and protozoa may also harbor pathogenic and nonpathogenic bacteria, either internally or attached to their surfaces, and this association provides the bacteria with some degree of protection from the inactivation by disinfectant residuals. http://www.epa.gov/ogwdw/disinfection/tcr/pdfs/whitepaper_tcr_biofilms.pdf

Information about the development and control of biofilms in drinking water is sparse (EPA, 1992). In addition, there is meager data on other issues related to biofilms, including the role of iron and sulfur bacteria in biofilm development, the role of biofilms in the corrosion of pipe material, the role of biofilms in nitrification for systems that use chloramines as a secondary disinfectant, and the effect of added corrosion inhibitors on bacterial populations in biofilms.

The presence of chlorine or chloramine retards the development and affects the spatial distribution of biofilm. The type of disinfectant residual provided selects for bacteria that are more tolerant to the specific disinfectant used. The biofilm environment provides protection for the cells by diffusional resistance and neutralization of the disinfectant. Therefore, biofilm organisms are less inhibited by the disinfectant residual than are planktonic cells. Differential effectiveness of chlorine and monochloramine for control of biofilm growth has been shown. Monochloramine, because it is less reactive and therefore more persistent, apparently can penetrate the biofilm and is more effective than chlorine in controlling biofilm growth.

In some cases, coliforms that gain entry into the distribution system may attach to pipes or pipe sediments and proliferate, thus becoming a biofilm constituent. The intermittent, sporadic, or persistent sloughing of coliform bacteria from biofilms into the water of the distribution system may cause systems to repeatedly violate standards for total coliforms. This problem is most frequently associated with utilities that use a surface water supply where the water temperature is $\geq 15^{\circ}\text{C}$. Public safety dictates that all coliforms detected by testing be regarded as representing system vulnerability, unless strong evidence suggests otherwise.

The utility should review its treatment operations and increase monitoring of the quality of water entering the distribution system to be sure that inadequate or failed treatment is not responsible for the total coliform occurrences and that *E. coli* is not

present in the water. The water utility should also review the operation and management of the water distribution system to ensure the absence of *E. coli*, a disinfectant residual is present, an adequate cross connection control program is in effect, and maintaining adequate pressure to prevent intrusion of microbial contaminants. Finally, the water utility should insure that large volumes of water held in storage in reservoirs, standpipes, or above ground tanks are not the source of the total coliform problem.

During warm-water periods, it is more difficult to maintain a disinfectant residual in the water in all parts of the distribution system. With increasing temperature, the disinfectant reacts more rapidly with dissolved organic chemicals in the water and in the biofilm, and bacteria grow faster. Increased reaction rates and bacterial growth are often compounded by a lack of knowledge of system hydraulics and of the actual water movement throughout the system. In many cases, there are large areas where minimal movement of the water occurs. Many water utilities may create microbial or chemical contaminant problems by their failure to understand how their systems work; better system management can reduce those problems.

Biofilms in household and building plumbing systems

Biofilms develop in household and building plumbing systems and can degrade water quality more rapidly and to a greater extent than in the distribution mains. In such systems, pipe materials, long residence times, stagnation/ low-flow conditions, residual disinfectant concentration and water temperature may differ considerably from those found in the main distribution piping. Increased disinfectant consumption in household and building networks may be related to the smaller diameters of service line piping, which results in a greater surface-to-volume ratio than in the pipes of the main distribution system. Depletion of the disinfectant residual due to water stagnation, organic deposits on the pipe surfaces and increased water temperature result in increased biofilm bacterial growth.

In general, there is little evidence that high levels of heterotrophic bacteria in drinking water from plumbing systems have adverse health effects. However, for specific organisms such as *Legionella pneumophila* and nontuberculous *Mycobacterium* spp. that have been found as part of the biofilm in such systems, there is evidence of adverse health effects. Plumbing system components such as hot water storage tanks and shower heads may permit significant bacterial growth. For example, outbreaks of Legionnaire's disease in healthcare facilities have been related to amplification of *L. pneumophila* in hot-water storage tanks, shower heads and drinking waters used in dentistry.

In the case of nontuberculous mycobacteria, some evidence suggests that the type of residual disinfectant used in the drinking water treatment process may select for colonization of biofilms by these organisms, and species found in treated drinking water have been linked to human infections in immunocompromised patients.

Alternative Water Sources

In areas where both surface and ground-water sources may not be suitable as potable source water, other sources of drinking water may be necessary. Bottled water is one alternative source, but is very expensive and generates additional waste (plastic bottles); therefore this source of drinking water is not viewed as a sustainable long-term solution.

Bottled Water

The bacterial quality of noncarbonated bottled water varies both among brands and from lot to lot within a brand. Chemical quality varies as well. Bottled water in the United States is usually treated by RO, ozone, and/or ultraviolet light. Bacterial densities in noncarbonated bottled water, determined by plate count methods, vary from 0 to $>1.0 \times 10^5$ CFU ml⁻¹. Fresh noncarbonated bottled waters often have low bacterial densities, but during storage the bacteria can multiply, often by several orders of magnitude. Carbonated (sparkling) bottled waters generally have low or no detectable bacteria because of the low pH. In most bottled waters examined, coliform bacteria have been absent. Bottled water quality is regulated by the US Food and Drug Administration, but must comply with EPA drinking water regulations to the extent it is possible to do so. It should be noted that bottled water regulations include many of the same maximum levels as the drinking water regulations, although they do not include maximum levels for all regulated contaminants. For instance, FDA does not regulate contaminants that are considered primarily distribution system contaminants because bottled water is not subject to distribution system contamination potential (e.g., bottle water is not expected to contain *Cryptosporidium*).

Emergency Drinking Water

Treatment of water for drinking use in an emergency generally involves either boiling the water or chemically disinfecting the water using liquid chlorine laundry bleach, tincture of iodine, or iodine or chlorine tablets. Water to be disinfected should be strained through clean cloth to remove particles and floating matter.

Boiling is the most effective means of inactivating pathogens. For heat disinfection, the strained water should be boiled vigorously for at least one minute and allowed to cool before use. For chemical disinfection, add liquid chlorine bleach (6–8.25% chlorine) at a rate of two drops (clean clear water) or four drops (cloudy water) per quart, mix thoroughly, and allow to stand for 30 min. A slight chlorine odor should be detectable in the water; if not, repeat the dosage and let stand for an additional 15 min before using. If tincture of iodine is used, add five drops (clean clear water) or ten drops (cloudy water) of 2% tincture of

iodine solution per quart of water. Allow the water to stand for 30 min before use. For chlorine or iodine tablets (obtained from drug or sporting goods stores), follow the instructions on the package. Keep all purified water in clean closed containers. Chlorine and iodine may not inactivate the protozoan pathogens, especially *Cryptosporidium*.

Point-of-Use/Point-of-Entry Treatment

Point-of-use/point-of-entry treatment (POU/POE) devices (or filters) are small package units designed to treat water at a designated tap in a household or to treat all of the water entering the household. These devices are becoming increasingly sophisticated and are growing in popularity. POU devices are generally placed under a sink and POE devices might be located in a basement or a garage. Currently POU/POE treatment is used to reduce the levels of a wide variety of contaminants in drinking water, including organic material, turbidity, fluoride, iron, radium, chlorine, arsenic, nitrate, ammonia, and pathogens (including cysts/oocysts). Taste, odor, and color can also be improved with POU/POE treatment.

The types of technology that may be used in POU/ POE treatment devices include adsorption, ion exchange, RO filtration, chemical oxidation, distillation, aeration, and disinfection such as chlorination, iodination, ozonation, and ultraviolet light. Activated carbon filtration, a type of adsorption device, is the most widely used POU system for home treatment of water. The performance of an individual unit depends on a combination of factors, such as unit design, type and amount of activated carbon, and contact time of the water with the carbon. Most units use GAC in their design, although other types of carbon such as pressed block, briquettes of powdered carbon, and powdered carbon are available.

Bacterial growth in activated carbon units may be a problem. The organic material adsorbed onto the carbon provides nutrients for bacterial growth. Stagnation periods between operations allow time for bacteria to grow and high densities will develop in newly installed filters within 2 weeks. To help minimize this problem, some units contain GAC impregnated with silver or some other bacteriostatic agent. Silver, although useful against some bacteria (e.g., coliforms and related enteric bacteria) as a bacteriostatic agent, does not effectively inhibit the growth of all bacteria in GAC, POU, or POE filters. Bacterial levels in water leaving GAC filters, with or without silver, range from 10^2 to 10^5 CFU ml⁻¹, but it may take longer for bacterial levels in a GAC filter with silver to reach the higher concentrations. When a GAC filter is used as the key treatment technique and the incoming water is not microbiologically safe, water from the unit should be disinfected either chemically or by UV irradiation to reduce bacterial levels in the water and to inactivate opportunistic pathogens that may colonize the carbon particles. Silver resistant nontuberculous mycobacteria have been shown to colonize point of use water filters containing silver, suggesting a potential risk to immunocompromised persons who consume water from such devices.

Some carbon block units do not contain silver but claim bactericidal effects, probably due to straining through small carbon pore size (0.5 µm). Some POU/ POE systems use a disinfectant such as ozone or UV irradiation to control bacteria.

Household Water Treatment in Developing Countries

Developing countries often lack the resources for the types of water treatment systems used in developed countries. The WHO, US Centers for Disease Control and Prevention, and other organizations are developing and testing simple and inexpensive alternatives that households in such countries can use to control waterborne disease. Among the more promising alternative disinfection methods being tested and used are boiling, solar disinfection using clear plastic containers (combined UV radiation and thermal effects), solar disinfection using dark, or partially dark, opaque containers (thermal effects alone), UV lamps, chlorine tablets, and liquid solutions of sodium hypochlorite.

Sometimes, a filtration process is needed, given that high organic matter levels in the water affect chlorine efficiency and high water turbidity levels affect UV treatment efficiency. Simple filtration processes used by households in the developing regions include adsorption by clay, activated carbon, charcoal, porous ceramic filters, fibers, cloth, paper, and crushed vegetative matter such as seeds. To minimize post-treatment contamination, the WHO recommends household water storage in narrow-mouth containers with a spigot or spout.

The candidate treatment alternatives mentioned above are by no means exhaustive. The alternative selected depends upon such issues as raw water quality, treatment effectiveness and reliability, and availability of resources such as electricity (e.g., for UV lamps), wood or other fuel (for boiling water), and hours and days of sunlight per year (solar heating). It also depends upon broader issues such as affordability, technical simplicity, education level, cultural acceptance of candidate alternatives, and the prospect for continuing the use of candidate alternatives over time. More information on household treatment systems in developing countries is available at <http://www.who.int> and <http://www.cdc.gov>.

Other Issues Associated with Water Treatment

Drinking Water Microbial Diversity

Traditionally, the microbial water quality of distribution systems has relied on culture-based methods that target fecal indicator bacteria and heterotrophic bacteria. Disinfectants can kill most of the pathogenic microorganisms and the surrogate indicators but a fraction may persist and not accounted for as they lose their ability to grow on selective media. Some drinking water bacteria may enter a viable but nonculturable (VBNC) status, although the health risks impacts of VBNC bacteria is poorly understood.

Additionally, the bacterial composition of drinking water has been based solely upon bacteria that can form colonies on agar media under a narrow set of incubation conditions. Only a small fraction of the bacterial community can grow under such conditions, resulting in a biased picture of the *in situ* microbial diversity. A similar situation holds for the viruses and fungi. Moreover, there are no culture-based methods to detect or enumerate some microbial groups relevant to public health (e.g., noroviruses). Detection of protozoan parasites normally relies on the use of cumbersome and time-consuming microscopic techniques.

Recently developed molecular tools have circumvented some of the aforementioned limitations and have deepened our understanding of the microbial community dynamics in water distribution systems. For example, DNA-based sequence analyses of the 16S rRNA gene have revealed a rather complex microbial community composed of different bacterial groups, mostly dominated by alpha-, beta-, and gamma-Proteobacteria and Actinobacteria (primarily mycobacteria) species (Figures 2 and 3). These methods have shown that the bacterial community structure can vary within a distribution system. Moreover, the bacterial community is dynamic as it can change from season to season and in response to changes in disinfectant. Eukaryotic microorganisms have also been identified using similar approaches. Among some of the eukaryotes identified are different amoebae, ciliate, metazoan, fungi, and cercozoan species. Next generation sequencing methods are now used in conjunction with barcoded primers to simultaneously describe the composition of hundreds to thousands of drinking water samples simultaneously. This facilitates addressing complex questions via robust experimental design. Sequence analyses and databases are not only important to confirm the identity of the residing microbiota but also to develop novel methods that specifically detect the different microbial groups that reside in distribution systems.

Several methods have been used to detect microbes in drinking water, often aided by the amplification of specific genetic markers via polymerase chain reaction (PCR). Such methods have detected bacteria closely related to public health-relevant genera such as *Legionella* and *Mycobacterium* in drinking water (Figure 2). While species of the latter genera have been associated with waterborne illness, their detection does not necessarily imply a health risk or a deficiency in water treatment, as most species within these genera are not pathogenic to humans. Nucleic acid-based methods have also detected fastidious organisms in drinking water such as nitrifying bacteria, whose presence may degrade drinking water quality and thus may reflect inadequate water treatment practices.

Studies using methods targeting phospholipid fatty acids and RNA have demonstrated that different disinfection treatments (i.e., chlorination vs. chloramination) modify the characteristics of the active and dynamic microbial community in drinking water biofilms. Unlike DNA, microbial phospholipid fatty acids and RNA are thought to degrade fairly rapidly in environmental settings and thus their detection can be used as evidence for the presence of metabolically active cells and hence disinfection efficiency in drinking water. For most bacterial groups phospholipid analyses however do not provide the resolution needed to identify bacteria at the species level. Thus the use of RNA based methods to identify active bacterial species promises to be an important tool in the future of drinking water microbial water quality (Revetta et al 2010). RNA has also been shown to increase the detection limits of fecal bacteria in treated source water (Pitkänen et al., 2013).

The advent of next generation sequencing methods is providing other unique opportunities such as the possibility of sequencing the entire genome of different microbial species autochthonous to distribution systems. Understanding the genetic makeup of autochthonous bacteria can lead to a better understanding of their survival capabilities, discovery of factors that can be used to promote their growth in artificial media, how they might interact with other members of the community, and their potential link to health risks. Novel sequencing methods are now also used to get an idea of all the different genes associated with a microbial sample (metagenomics) as well as the genes that are transcribed (metatranscriptomics). Metagenomic studies have already provided a significant amount of information on the genetic functional network in a sample, including the presence of antibiotic resistance mechanisms that would have been difficult to unveil (Gomez-Alvarez et al., 2012)). Metagenomic sequencing can also help us construct entire microbial genomes without the need of relying on the culturability of the organism or availability of culturable methods. In the future, metatranscriptomics will be of great value at assessing which metabolic pathways are responding to the different drinking water conditions and to further confirm the identity of the active microbial members within drinking water samples. For those bacterial pathogens that interact with amoeba, metagenomic sequencing will help better understand the genes responsible for infectious pathways and to survival mechanisms with host cells.

Source Water Protection

Preventing the pollution of waterbodies that serve as sources of drinking water (e.g., groundwater, lakes, and rivers) is becoming an important challenge to both developed and developing countries. Source water pollution has a direct impact on treatment plants, particularly as the level of pollution can have an effect on the removal and disinfection efficiency of enteric pathogens and their eventual presence in the distribution system. In the United States, under the Clean Water Act, each state sets water quality standards that include limits on the concentration of specific pollutants that can be present in an ambient water body (usually a lake or a river) and this limit depends on its designated use (e.g., swimming, boating, fishing, drinking water source, and shellfish harvesting). To limit pathogens, fecal indicator bacteria such as *E. coli* or enterococci are normally used. Discharges of the fecal indicator into that water body are set at levels that meet water quality standards. One goal of this requirement is to limit the level of fecal matter that reaches a water system intake. This limit facilitates treatment and reduces the health risk in the event of a treatment failure. In spite of these standards, a significant portion of US surface waters exceeds regulatory limits.

Figure 2 Phylogenetic affiliation of 16S rRNA sequences recovered from bulk water metagenomes: chloraminated (CHM, green) and chlorinated (CHL, red). Reads were identified by phylum [p], class [c], order [o], and family [f]. The tree was inferred using maximum likelihood analysis of aligned 16S rRNA gene sequences.

Figure 3 Phylogenetic relationships among the ten most abundant operational taxonomic unit (OTU) groups from each groundwater (GW, □) and surface water (SW, ▴) communities that explained $\approx 68\%$ (SIMPER analysis) of the dissimilarity within all samples (one-way ANOSIM, $R=0.134$, $p=0.034$). The tree was inferred from a maximum likelihood analysis of aligned 16S rRNA gene sequence (≈ 800 bp); nodes with a bootstrap value $\geq 50\%$ of 500 replicates are identified.

Several microbial source tracking (MST) methods have been developed to identify the primary sources of pollution and to establish adequate pollution control practices (Santo Domingo et al., 2007). The use of MST data could lead to measures that decrease the level of enteric pathogens entering water bodies used by drinking water systems. Many MST methods have been proposed in the last 15 years, but those that detect host-specific markers directly from water DNA extracts have gained the most acceptance. Such MST methods are based on quantitative PCR (qPCR) and usually target the 16S rRNA gene of fecal bacteria within the Bacteroidales. A reliable MST assay must target populations that do not grow in the environmental waters, exhibit high levels of host specificity and host distribution, target markers that are present in high abundance within the specific fecal source, cross-react with markers that are present in low abundance within non-specific sources, detect targets present at low levels within a water sample, exhibit geographic stability and be seasonal. Ideally, an MST method should also correlate with the presence of the

indicator that is used as the water quality standard for the drinking water source. Unfortunately, there is no perfect MST assay and therefore, whenever possible, multiple assays should be used to determine the primary sources and to quantify their relative fecal bacteria loading contributions.

Homeland Security

Concerns regarding the vulnerability of municipal water supplies to biological attacks have prompted renewed interest in treatment issues, particularly as they relate to the survival of select agents in potable water (e.g., *Bacillus anthracis*, *Francisella tularensis*, and smallpox virus). Data on the inactivation of bacterial bioterrorism agents by chlorination are available. The detection of bioterrorism agents in drinking water requires methods with low detection limits as these agents need to be detected at very low densities, given that they have low infectious doses. As a result, future early warning detection systems will rely on the development of efficient concentration methods as well as rapid molecular procedures with low detection limits (e.g., polymerase chain reaction assays).

Conclusions

Overall, the treatment technology available today is capable of providing microbiologically safe drinking water to all consumers. In practice, however, many systems are still vulnerable to waterborne disease. Reasons include (1) inability to fund the installation and use of adequate technology, (2) ignorance of the need for adequate technology, (3) inadequate or improper monitoring to insure that barriers against waterborne disease remain intact, (4) lack of real-time monitoring data, and (5) lack of adequate data on the effectiveness of various treatment practices against certain pathogens. Degrading infrastructure is another significant issue which will become more critical in coming years. In addition, with increased population pressure, source water quality may decline over time, especially in areas where water is scarce; thus the technology used becomes inadequate. These problems are common on a global basis. The challenge globally is to highlight the imperative of safe drinking water and to find solutions to these problems.

Drinking Water Microbiology

Marylynn V Yates, University of California, Riverside, CA, United States

Introduction

Access to clean drinking water is required for healthy, thriving communities. It is estimated that more than 5 billion people (71% of the global population) used what the WHO has defined as a safely managed drinking water service (Fig. 1); that is, one located on premises, available when needed and free from contamination. Unfortunately, in 2015, 29% of the global population (2.1 billion people) lacked safely managed drinking water services—defined by the World Health Organization (WHO) as water at home, available, and safe. There were 844 million people in the world who lacked a basic drinking water service, which is defined as drinking water from an improved source, provided that the collection time is not more than 30 min for a round trip, including the time standing in line waiting. Fig. 2 shows the regional differences in access to different types of water across the world.

Concern over the lack of access to safe drinking water led the WHO/UNICEF Joint Monitoring Program to establish the goal to “Ensure Availability and Sustainable Management of Water and Sanitation for All” as its Sustainable Development Goal (SDG) 6, with a target of achieving “universal and equitable access to safe and affordable drinking water for all” by 2030. Further, they have defined safe drinking water as water that “has a risk level equal to or less than a 1 in 10,000 annual probability of infection or 1 in 1 million disability-adjusted life years” (DALY).

Significance of Waterborne Disease

On a global basis, every year, 1.5 million people die from waterborne disease. The majority of these individuals are young children who die of dehydration caused by diarrhea. According to the World Health Organization, there are almost 1.7 billion cases of diarrhea in young children annually, and diarrhea is the second leading cause of death for children under 5 year of age.

In the United States and other countries in which drinking water treatment is routinely practiced, people typically assume that all drinking water is treated, however, that is not the case. For example, in the United States, the Environmental Protection Agency (EPA) estimates that 15% of the population obtains their drinking water from untreated private wells or other untreated sources. Based on statistics compiled by the Centers for Disease Control and Prevention, most of the drinking water outbreaks in the United States are associated with untreated or inadequately treated ground water, and distribution system deficiencies. For example, in the latest update on waterborne outbreaks in the United States (2013–14), the CDC reported 1006 cases of illness, 130 of which were caused by *Legionella*, and 86% of which originated from outbreaks in which acute gastrointestinal illness was the predominant illness. Epidemiological investigations have estimated that between 12 million and 19.5 million waterborne illnesses occur annually in the United States, only a small fraction of which are recognized and/or reported.

Waterborne Pathogens

Worldwide, it is believed that the most common route of infection with a waterborne pathogen is the “fecal-oral” route: infection occurs as a result of exposure to water or food improperly treated sewage or directly contaminated with untreated human or animal feces. Such microorganisms are referred to as enteric pathogens.

Although other microorganisms (e.g., *Legionella*, *Naegleria*) can cause waterborne disease, most of the concern and focus on a global basis has been on microorganisms of enteric origin. Much of the reason for this is that many of these microorganisms can be readily handled through the implementation of relatively simple interventions such as handwashing and other sanitation measures.

The fecal material of infected individuals is the major source of pathogenic microorganisms in domestic wastewater: hundreds of different types of microorganisms may be present in the fecal material of infected humans and animals. In addition, urine may be a source of certain pathogenic microorganisms, such as *Leptospira* and polyomaviruses. Numerous factors affect the concentrations and types of pathogens found in domestic wastewater at any given over time; these include the disease incidence in the population producing the wastewater, season of the year, climate factors (such as rainfall, temperature), the amount of water being used, the economic status of the population, and quality of the drinking water. If fecal material or wastewater contaminated with fecal material enters a water body that is used as a source of potable water, there is a potential for disease transmission. The major groups of pathogenic microorganisms transmitted by water and food contaminated with feces include bacteria, viruses, and parasites.

As stated previously, other, nonfecal microorganisms also cause waterborne disease from the consumption or use of potable water; these are typically microorganisms indigenous to the water or sediment. For example, *Legionella*, a bacterium that is transmitted via aerosols, is a frequent cause of drinking-water associated disease. Indeed, in 2001, the CDC began including reports of *Legionella* outbreaks with the drinking water surveillance data, and *Legionella* was the most frequently-identified causative agent of waterborne disease in reported outbreaks in the United States in 2013–14. Notably, it was responsible for all 13 of the deaths

Fig. 1 Population using drinking water sources meeting SDG criteria for safely managed services, 2015 (WHO/UNICEF, 2017).

Fig. 2 Regional drinking water coverage, 2015 (WHO/UNICEF, 2017).

associated with waterborne disease in that time period. *Naegleria fowleri*, an amoeba that naturally occurs in the sediments of certain warm water bodies, has also been reported as the cause of several waterborne disease outbreaks. Infection by this microorganism typically results in death. A series of fact sheets that describe the human health effects, source and occurrence, routes of exposure, and significance in drinking water for many waterborne pathogens has been compiled by the World Health Organization.

Bacteria

Bacteria are naturally present in the gastrointestinal tracts of humans and animals; in fact, they are necessary for the proper functioning of the digestive system. The vast majority of these bacteria are harmless. However, when an individual is infected by an enteric bacterial pathogen, these microorganisms grow and reproduce in the gastrointestinal tract, and they are shed in the fecal material. Because the enteric bacteria are well-adapted to the conditions present in the gastrointestinal tract, which include high organic carbon concentrations, low pH, and a relatively high temperature ($\sim 37^{\circ}\text{C}$), they tend to have a relatively difficult time growing in the environment. This is because the conditions in soil, water, etc. are generally very different from those in the gastrointestinal tract: nutrients are generally present in low concentrations and/or in difficult-to-metabolize forms, the temperature is not optimal for growth, the moisture content is lower, etc. As a result, the enteric bacteria typically do not compete well with the indigenous soil or water bacteria for the available nutrients. This adversely affects their ability to reproduce, or even survive without reproducing, in the environment. Thus, their longevity in the external environment is typically limited to a few days to weeks, depending on the environmental conditions.

Historically, the bacterial pathogens have been the focus of waterborne disease, mainly because they were among the first microorganisms recognized. Bacteria cause many diseases, such as cholera, typhoid, and dysentery that have been responsible for

large epidemics (and, in the case of cholera, pandemics) all over the world. In general, many of the bacteria pathogens are relatively easy to remove through wastewater and drinking water treatment processes, and, therefore, are of less concern than the other groups of pathogens in many industrialized countries. However, these pathogens are still of great concern in many of the less-industrialized countries, due to the lack of adequate sanitary treatment processes in those countries. According to the WHO/UNICEF, in 2015 only 39% of the global population (2.9 billion people) used a safely managed sanitation service; that is, excreta safely disposed of in situ or treated off-site. More than 2 billion people lack basic sanitation, and almost 1 billion people still practice open defecation.

Some of the most common bacterial pathogens found in human and animal waste that are transmitted by contaminated water and food are listed in [Table 1](#). Some relevant characteristics, such as infectivity, survival in water, resistance to chlorine, and health impacts are also provided.

Viruses

Although fecal material always contains high concentrations of nonpathogenic bacteria because they are part of the normal flora of the gastrointestinal tract, like pathogenic bacteria pathogenic viruses are typically only present in fecal material if the individual is infected. Enteric viruses are very different from enteric bacteria in a number of ways. Some of the most important differences in this context are:

- Viruses are nonliving. They can only reproduce inside of susceptible host cells, as they use the host's biochemical mechanisms to reproduce themselves.
- Viruses are relatively more host-specific than bacteria. Thus, many viruses are only able to infect a single species or a few species. This can make it easier to identify the source of contamination. For example, if a human-specific virus is found in water, it is clear that the water has been contaminated by human fecal material.
- Because viruses are metabolically inert when outside of a host cell, they are not affected as much as bacteria by the presence of nutrients in the external environment. As they cannot reproduce in the environment, their numbers can only decrease over time.
- Viruses are typically able to survive for longer periods in the environment, compared to bacteria. Typically, viruses can survive for weeks to months; survival has even been reported for 2 years in a cold groundwater.
- Viruses are much smaller than bacteria. The typical enteric virus is 25–80 nm in size, while the typical size of an enteric bacterium is 1–2 μm . This affects their ability to be transported through the soil and into the groundwater.

More than 100 types of enteric viruses can be present in domestic wastewater. The types of symptoms that result from enteric virus infections range widely—from asymptomatic infections to relatively mild, self-limiting diarrhea, to more severe illnesses, including respiratory illness, infectious hepatitis, paralysis, encephalitis, and myocarditis. Several of the pathogenic human enteric viruses, along with some relevant characteristics, such as infectivity, survival in water, resistance to chlorine, and health impacts, are listed in [Table 1](#).

Parasites

Another group of pathogenic microorganisms that can be transmitted through contaminated drinking water is the parasites. This is an extremely diverse group of organisms, the common feature of which is that they live on or in a host organism and obtain their food from or at the expense of the host. The enteric parasites that are pathogenic to humans can be classified into two groups: the protozoa (sometimes referred to as the protists) and the helminths, which include the intestinal worms. Protozoa are single-celled microorganisms whose life cycles include at least one vegetative as well as at least one resting stage. The infective stage of the protozoa is different for different parasites. In the case of *Cryptosporidium*, the resting oocyst form must be ingested to initiate infection; for others, the vegetative form must be ingested for infection to occur. The resting stage of the organism (cyst, ovum) is generally relatively resistant to inactivation from environmental stresses and during conventional drinking and wastewater treatment processes. Thus, those parasites whose resting stage is the infective stage may be of greater concern than those whose infective form is the vegetative stage, even for consumers of (inadequately) treated water.

Many of the intestinal protozoa are transmitted by fecally-contaminated water, food, or other materials. Some of the most common protozoan pathogens found in human and animal waste that are transmitted by contaminated water and food are listed in [Table 1](#). Some relevant characteristics, such as infectivity, survival in water, resistance to chlorine, and health impacts are also listed.

Indicators of Fecal Contamination of Water

As stated previously, bacteria are always present in the gastrointestinal tract of humans and other animals, and therefore are present in fecal material. On the other hand, pathogenic enteric microorganisms are typically only present when an individual is infected. Therefore, if one wants to assess the safety of water for human consumption, the water would have to be continuously monitored for the presence of pathogens in order to be certain of their presence or absence. Additionally, there are hundreds of different pathogens that may be present in feces, so the water would need to be monitored for all of these microorganisms to assure the safety for consumption.

Table 1 Selected pathogens that can be transmitted by water

Organism	Disease	Incubation Period	Duration of Illness	Health Significance ^a	Resistance to Chlorine ^b
Bacteria					
<i>Burkholderia pseudomallei</i>	Pneumonia			High	Low
<i>Campylobacter</i>	Gastroenteritis	3–5 days	1–4 days	High	Low
<i>Legionella</i>	Pontiac fever	5–66 h	2–7 days	High	Low
	Pneumonia	2–14 days	Weeks to months	High	Low
<i>Leptospira</i>	Weil's disease (headache, chills, fever, nausea, neck or joint pain)	2–20 days	3 days to 3 weeks	High	Low
Shiga-toxin producing <i>E. coli</i>	Gastroenteritis, hemolytic uremic syndrome, kidney failure	12 h – 8 days	1 day to 3 weeks	High	Low
<i>Salmonella enterica</i> serovar typhi	Typhoid fever	7–28 days	Weeks to months	High	Low
<i>Salmonella</i>	Salmonellosis	8–48 h	3–5 days	High	Low
<i>Shigella</i>	Bacillary dysentery	1–7 days	4–7 days	High	Low
<i>Vibrio cholerae</i> O1	Profuse, watery diarrhea, vomiting, rapid dehydration	9–72 h	3–4 days	High	Low
<i>Vibrio cholerae</i> non-O1	Watery diarrhea	1–5 days	3–4 days	High	Low
<i>Yersinia enterocolitica</i>	Gastroenteritis	2–7 days	1–21 days	Moderate	Low
Protozoa					
<i>Cryptosporidium parvum</i>	Diarrhea	1–2 weeks	4–21 days	High	High
<i>Cyclospora cayatanensis</i>	Watery diarrhea alternating with constipation	2–11 days	days	High	High
<i>Entamoeba histolytica</i>	Amoebic dysentery	2–4 weeks	weeks to months	High	High
<i>Giardia intestinalis</i>	Diarrhea, malabsorption	5–25 days	weeks to months	High	High
<i>Microsporidium</i>	Chronic diarrhea, weight loss				
<i>Naegleria fowleri</i>	Primary amoebic meningoencephalitis	Minutes to hours		High	Low
<i>Toxoplasma gondii</i>	Toxoplasmosis			High	High
Viruses					
Adenovirus	Respiratory illness, conjunctivitis, vomiting, diarrhea	1–4 days	2–3 days	Moderate	Moderate
Astrovirus	Vomiting, diarrhea	3–4 days	2–7 days	Moderate	Moderate
Calicivirus	Vomiting, diarrhea			Moderate	Moderate
Coronavirus	Vomiting, diarrhea			Moderate	Moderate
Enterovirus:		3–14 days	variable		
Poliovirus	Paralysis, meningitis, fever			High	Moderate
Coxsackie A	Meningitis, fever, herpangina, respiratory illness, paralysis			High	Moderate
Coxsackie B	Myocarditis, congenital heart anomalies, rash, fever, meningitis, respiratory illness, pleurodynia			High	Moderate
Echovirus	Meningitis, encephalitis, respiratory illness, rash, diarrhea, fever, myocarditis, endocarditis			High	Moderate
Enterovirus 68–71	Meningitis, encephalitis, respiratory illness, acute hemorrhagic conjunctivitis, fever			High	Moderate
Hepatitis A virus	Infectious hepatitis	15–50 days	1 week to several months	High	Moderate
Hepatitis E virus	Hepatitis	15–65 days	1 week to several months	High	Moderate
Norovirus	Epidemic vomiting and diarrhea	1–3 days	1–3 days	High	Moderate
Reovirus	Respiratory illness			Moderate	Moderate
Rotavirus	Diarrhea, vomiting	1–3 days	3–7 days	High	Moderate
Sapoviruses	Gastroenteritis			High	Moderate

^aHealth significance relates to the severity of impact, including association with outbreaks.^bWhen the infective stage is freely suspended in water treated at conventional doses and contact times and pH between 7 and 8. Low means 99% inactivation at 20°C generally in <1 min, moderate 1–30 min and high >30 min. It should be noted that organisms that survive and grow in biofilms, such as *Legionella* and mycobacteria, will be protected from chlorination.

Modified from Yates, M. V. (editor in chief) (2016). Manual of Environmental Microbiology, 4th ed. American Society for Microbiology, Washington, DC. 1088 pp.

However, it is not technically or economically feasible to test wastewater for the presence of all different types of pathogens, nor is it feasible to continuously monitor water for pathogenic microorganisms. As a consequence, the microbiological quality of water historically has been assessed by monitoring for the presence of alternative organisms—those enteric organisms that are always present in fecal material—the so-called indicator microorganisms. The rationale for using fecal indicator microorganisms is that, if they are found in water, the water contains fecal material, and therefore may also contain pathogenic microorganisms. In contrast, if fecal indicators are absent, the water is considered not to be contaminated by fecal material, and therefore, no fecal pathogens are present. Common indicators or groups of indicator organisms used are the total coliform bacteria, the thermotolerant coliform bacteria (also called fecal coliform bacteria), the enterococci (also called fecal streptococci); examples include *Escherichia coli*, *Clostridium perfringens*, and *Bifidobacterium*.

While the initial focus of monitoring water for safety was on the potential presence of pathogenic bacteria, in industrialized countries, many of the bacterial diseases have been controlled through the use of drinking water and wastewater treatment, including disinfection. As this has occurred, more of the focus in drinking water and wastewater treatment has been on controlling the concentrations of parasitic and viral pathogens. Unfortunately, the bacterial indicators mentioned above do not always correlate well with the presence or behavior of the nonbacterial pathogens. Efforts are underway to identify more appropriate indicators, such as bacteriophages (viruses that infect fecal indicator bacteria) for these pathogens.

Characteristics of Microbial Indicators

In 1966, Bonde developed the first systematic delineation of the attributes of an ideal indicator organism for the assessment of health risk or treatment efficiency. These criteria state that an ideal indicator should:

- Be present whenever the pathogens are present;
- Be present only when the presence of pathogens is an imminent danger; that is, they must not proliferate to any greater extent in the aqueous environment;
- Occur in much greater numbers than the pathogens;
- Be more resistant to disinfectants and to the aqueous environment than the pathogens;
- Grow readily on simple media;
- Yield characteristic and simple reactions enabling as far as possible an unambiguous identification of the group;
- Be randomly distributed in the sample to be examined, or it should be possible to obtain a uniform distribution by simple homogenization procedures; and
- Grow widely independent of other organisms present, when inoculated in artificial media; that is, the indicator bacteria should not be seriously inhibited in their growth by the presence of other bacteria.

Unfortunately, no indicator organism or group of organisms was found to have all of these attributes. The criteria that have been most difficult to meet are the first and fourth: many waterborne disease outbreaks have occurred in the absence of indicator microorganisms, which, at least in some cases is due to the fact that the pathogens are less resistant to disinfectants and environmental stressors than the indicator microorganisms. This is especially true for nonbacterial pathogens.

Over time, as new pathogens are identified, more/different applications for indicators have been found, and new microbial sampling and detection methods have been developed, Bonde's criteria have been reevaluated. For example, a National Academies of Science committee developed a set of criteria recommended for use when assessing the appropriateness of any indicator or group of indicators. These separate the biological attributes of the indicators themselves from the attributes of the methods used to detect the indicators. The desirable biological attributes of indicators, as developed by the NRC are:

- Correlated to health risk
- Similar (or greater) survival to pathogens under environmental conditions
- Similar (or greater) transport to pathogens
- Present in greater numbers than pathogens
- Specific to a fecal source or identifiable as to source of origin

The desirable attributes of the indicator detection methods, according to the NRC, are:

- Specificity (independent of matrix effects)
- Broad applicability
- Precision
- Adequate sensitivity
- Rapidity of results
- Quantifiable
- Measures viability or infectivity
- Logistical feasibility

For most situations, there is agreement that the most important characteristic of any indicator or indicator system is its ability to indicate possible health risk. This characteristic can be shown directly through conducting epidemiological studies in which the association between the indicators and health outcomes are assessed. A different, more common, and generally less expensive way

to demonstrate the correlation between indicators and health risk is to monitor water for the presence and/or concentration of pathogen and compare those data to data on potential indicator microorganisms. While the latter approach might be simpler and less expensive, it may be more problematic. This is because most pathogen detection methods detect a single pathogen or closely related group of pathogens, and a correlation (or lack thereof) between an indicator and a single pathogen or pathogen group does not infer that a correlation exists (or does not exist) with other waterborne pathogens. To obtain complete and accurate information regarding the potential for an indicator to provide information on the microbiological safety of the water, correlations for each pathogenic microorganism or related group of microorganism would need to be examined.

Common Indicators

It is technologically, economically, and practically not possible to test water for all possible pathogenic microorganisms. As a result, the typical practice has been, and continues to be, to monitor water for one or more indicator microorganisms (or groups of indicator microorganisms) to indicate whether or not there is a health risk associated with the consumption of water. Different groups have been used for many years as indicators of the microbiological quality of drinking water and of recreational waters. For example, total coliform bacteria have been used for almost a century to assess the microbiological quality of drinking water.

Coliform bacteria

The group of indicator microorganisms in longest use for assessing the microbiological quality of drinking water and wastewater is the total coliform bacteria. More recently, other coliform bacteria, including the thermotolerant coliforms (previously termed fecal coliforms and a subgroup of the total coliforms), and *E. coli*, a specific thermotolerant coliform bacterium, considered specifically of fecal origin, have been added to the commonly used indicator organisms. The US Environmental Protection Agency requires the monitoring of all public sources of drinking water for total coliform bacteria. The use of the total coliform standard to assess the microbiological safety of water has had a dramatic effect on reducing waterborne disease outbreaks in countries that have implemented one.

Numerous studies, however, have documented that many pathogenic microorganisms, especially enteric viruses and parasites, are not as easily inactivated by water and wastewater treatment processes as are coliforms. The fact that waterborne disease outbreaks continue to occur every year in countries that have implemented coliform monitoring standards is clear evidence that better ways to assess the microbiological quality of water must be found. Although there is no perfect indicator organism, research is ongoing to find a rapid, relatively inexpensive, and accurate way to assess the microbiological quality of water.

Fecal enterococci

Like the coliform bacteria, the fecal enterococci or fecal streptococci, which include some members of the genera *Streptococcus* and *Enterococcus*, are found in the intestinal tract of humans and many animals. Use of this group of organisms has some advantages over the coliform group for assessing the microbiological safety of water. These include the fact that they rarely multiply in environmental waters, they are more resistant to treatment processes and environmental stresses, and they generally persist for longer in the environment than do the coliform bacteria. The most common use for these organisms is to indicate the microbiological quality of recreational bathing waters. In addition, enterococci are recommended as one of the groups of fecal indicator organisms that can be used to assess the microbiological quality of groundwater by the US Environmental Protection Agency.

***Clostridium perfringens* spores**

As indicated previously, the resting stages of many protozoan parasites are especially resistant to inactivation during water and wastewater treatment. Therefore, the use of bacterial indicator organisms may not provide accurate information regarding the presence of pathogenic parasites in water. The search for a surrogate organism for parasite removal during treatment processes has led to investigations into the potential use of *Clostridium perfringens* spores. These bacterial spores are present, typically in very low numbers, in human and animal feces. However, like the protozoans, they are relatively resistant to many forms of drinking water and wastewater treatment processes, so may be useful indicators for parasite and virus removal by treatment. *Clostridium* spores are used in conjunction with enterococci as secondary indicators of water quality in Hawai'i, due to problems with coliform regrowth in the warm temperatures of the tropical environment.

Heterotrophic plate count bacteria

Another group of bacteria that can be used to assess the microbiological quality of water, especially with respect to the efficacy of treatment processes, is the heterotrophic plate count (HPC) bacteria. The HPC is defined as "the number of aerobic and facultatively anaerobic bacteria that obtain their carbon and energy from organic sources." This is a very general test of the bacteriological quality of water, and both pathogenic and nonpathogenic microorganisms are enumerated, but they are not and cannot be differentiated from one another using this method. Studies to assess the health effects of consumption of water containing high HPC have not documented adverse health effects. In addition, some studies have found that the presence of HPC bacteria in water do not indicate potential adverse human health effects.

The numbers of HPC bacteria in a specific water are typically less useful than changes in the number at a particular location, as the change may indicate a problem with the water/wastewater treatment processes, a lack of integrity of the water distribution system, or the potential for bacterial regrowth in the system.

Bacteriophages

The large differences between the physical properties, especially size, of bacterial indicators and waterborne viruses has caused concern over the use of bacterial indicators to evaluate the virological quality of water, especially groundwaters. This has led to investigations of the use of bacteriophages, viruses that infect bacteria, as indicators for groundwaters used as drinking water sources. The US Environmental Protection Agency allows the use of bacteriophages as an indicator of fecal contamination of groundwater in the Ground Water Rule.

The topic of the diversity of life on the planet has always fascinated scientist (Erwin, 1991), and the diversity of microbes has become even more fascinating with the discovery of their ubiquity and the important role that they play in a variety of ecosystems. It is, however, difficult to delineate microbial species and to count them globally. Therefore, estimating their diversity and providing an inventory is very challenging. Recent estimations based on species abundance distribution suggest that there are 10^{12} microbial species on Earth (Locey and Lennon, 2016), while other estimates put the number as low as a few millions (Amann and Rosselló-Móra, 2016a,b). The findings are strongly debated (Amann and Rosselló-Móra, 2016a,b; Lennon and Locey, 2016; Willis, 2016) and a true estimate is yet to come. Microbial communities in most natural environments are composed of numerous individuals that are spread across a very large number of different species. For example, each drop of seawater (1 mL) can contain 500,000–1 million prokaryotic microbes (bacteria and archaea) that are distributed across hundreds of microbial species (Lozupone and Knight, 2007). Soils show similar patterns, with often higher number of microbes (5.5×10^7 cells/g of soil, Elshahed et al., 2008) and thousands of species (Lozupone and Knight, 2007). The fact that microbes are numerous and diverse is long known, but the extent of their diversity really started to be understood with the development of new sequencing technologies during the mid-2000s. With these new sequencing technologies, it became possible to probe the diversity of communities in a variety of environments, with data always revealing a tremendous number of taxa. Interestingly, the distribution of microbes within samples normally showed communities dominated by a few abundant taxa followed by numerous rare ones (Fig. 1). The extent of that diversity and the presence of numerous rare taxa naturally begs the question of the ecological role that so many different microbes can have within one environment.

Fig. 1 Schematic rank–abundance curve. The coverage depth of different methods used for studying the diversity of microbial communities is indicated: gel fingerprinting, clone libraries/sanger sequencing, metagenomics and high-throughput amplicon sequencing. The arbitrary threshold of 0.1% for the detection of rare-biosphere organisms is indicated. Reproduced with permission from Lynch, M.D., Neufeld, J.D., 2015. Ecology and exploration of the rare biosphere. *Nature Reviews Microbiology* 13, 217–229.

The term “rare biosphere” was coined in 2006 by Sogin et al. (2006). At the time, a new high throughput sequencing technology was just starting to be used and they were the first to apply the “454” pyrosequencing technology to study microbes in environmental samples. They sequenced deep sea samples and observed thousands of low-abundance taxa that made most of the observed community diversity. They suggested that members of the rare biosphere may eventually become dominant in response to environmental change. The same year Pedrós-Alió (2006a,b), published a review paper on the topic of microbial diversity in which he explored and discussed the concept of core versus rare species, which he named the “seed bank”. Members of the seed bank were hypothesised to have extremely low loss rates because their low abundances made them less prone to viral infection or death by predation. Rare taxa could be promoted from the seed bank to the core population if conditions became suitable for the growth of the particular taxon. Pedrós-Alió concluded with a very fascinating statement that said: “If it was true that all microbes are easily dispersed globally, the long tail of any ecosystem would include all of the microorganisms on Earth. In effect, the biodiversity of any ecosystem would be identical to the biodiversity on the planet.” Even though that assumption may be difficult to test, recent works do suggest that the global ocean contains a persistent microbial seed bank (Caporaso et al., 2012; Gibbons et al., 2013). However, the structure of the rare biosphere would appear to be much more complex than originally thought as we will now see.

The two founding papers on the rare biosphere (Pedrós-Alió, 2006a; Sogin et al., 2006) rapidly attracted the interest of microbial ecologists. The exciting definition of a new category of microorganisms, combined with the rapid development of relatively cheap sequencing technologies, paved the way for research on the rare biosphere that would cover both the taxonomical and functional aspects of the topic over a large range of ecosystems.

What is Rare?

The first thing to think when studying rare microorganisms is to find a way to define what is rare. Microbial communities are made of thousands of individuals that can be described through a range of tools that are evolving and changing fast with technological advances. Before 2006, microbial communities were studied with molecular tools that included fingerprinting, cloning and Sanger sequencing. All methods relied on amplification of DNA by PCR and often targeted the 16S or 18S rRNA gene as taxonomical marker. This approach first originated in the 70's with the work of Norman Pace and colleagues on the ribosomal gene (Pace, 1973). The power of that approach was revealed when Carl R. Woese revolutionised the field by using the ribosomal gene as universal marker for the classification of organisms. He demonstrated the strength of the method in 1977 when he first published a new classification of life that was separated in 3 domains (Woese and Fox, 1977) later defined as Eucarya, Bacteria and Archaea (Woese et al., 1990). The separation of life in 3 major domains is still used today. The 16S and 18S rRNA became gold standards in the field to describe microbial diversity (Lane et al., 1985), and were applied through two main approaches: fingerprinting and cloning/sequencing. Fingerprinting technics such as RFLP or DGGE gave a rapid overview of the composition of communities, but they did not provide the identity of microbes. Cloning and sequencing were needed to identify their taxonomy but the approach was time and cost consuming. The taxonomic resolution of the fingerprinting method was good, but it only allowed detection of the most common members of the communities (Fig. 1). It was said that only bacteria with occurrence >1% could be seen (Muyzer et al., 1993). As for cloning, the costs of the technique limited the number of sequences that could be obtained and often communities were described with less than 100 sequences. Sequences were grouped by similarity into operational taxonomical units (OTUs). Since uncultured bacteria cannot be defined as species, OTUs serve as species proxies when studying community composition. The methodological limitation of PCR-dependent techniques at the time led Pedrós-Alió to set the cut-off for separating abundant and rare taxa at 1% (Pedrós-Alió, 2006a). Bacteria that could at the time be retrieved by PCR approaches would be considered as the abundant members of the communities. They were the bacteria that were important and active in the ecosystem. The diversity and identity of rare taxa would then not or only seldom be accessed by molecular approaches. Only rare microorganisms that could be grown in enrichment or pure cultures could be identified. Thus, only very few rare microbes were described at the time and the composition of the rare biosphere remained a mystery.

The discovery of high throughput sequencing transformed the field of microbial ecology (Logares et al., 2012). Instead of a few tens or hundreds of sequences, microbial communities could now be described by thousands of sequences (6505 to nearly 23,000 sequences in the first study of Sogin et al. (2006)). The new sequencing techniques gave birth to the term “rare biosphere”, but, in that first publication, this community component was not defined by any threshold; instead, it was just described as low abundance taxa. Low abundance taxa were the ones that constitute the long tail seen in rank abundance curves (Fig. 1). The development of a new sequencing technology and the subsequent discovery of the extent of the diversity of natural microbial communities raised a debate about the role of PCR and sequencing bias in artificially creating microbial OTUs. Could the rare biosphere be actually the “fake biosphere”? (Reeder and Knight, 2009; Kunin et al., 2010). Following the advance in sequencing technologies, tools were developed to clean the sequences and ensure that the data represented true diversity (Huse et al., 2010; Quince et al., 2011). With increasing sequencing depth, the cut-off for defining rare microbes was pushed down to 0.01% (Fuhrman, 2009; Galand et al., 2009; Logares et al., 2014a), but varied according to studies and sequencing depth up to 0.1% (Quero and Luna, 2014) or 1% (Campbell et al., 2011; Alonso-Sáez et al., 2015). The cut-off, and thus the definition of the rare biosphere, has been until now set arbitrarily and is dependent on the tool used for the study. In addition, it should be noted that defining abundance should be done within a common spatial or temporal scale. Microbes can be classified as rare within one sample, which is the most common case, but they can also be defined across a number of samples within a common environment, but at different time points, or within a

common time frame but at different locations. The scale used to define rarity will strongly impact the result of the analysis. An interesting thought is that even though a bacteria can be rare in one marine sample, e.g., 1 cell per liter, at the whole ocean level, it would not be that rare since 93,300,000,000,000,000 cells would be expected in the whole ocean roughly. With that in mind, one could think of a theoretical number for the whole ocean below which a species is rare.

Crespo et al. (2016) attempted to exhaustively map the rare biosphere in two marine samples by conducting very deep sequencing (~500,000 final reads per sample). Even with that sequencing depth, they were not able to cover the full diversity of the water samples and they calculated that ~2 million final reads would be adequate to sequence 90% of the total identifiable bacterial species richness. In an attempt to move forward and away from the sequencing depth-dependent definition of rarity, Kalenitchenko et al. (2018b) recently set up an experiment that use bacterial cell numbers to define rarity. The principle of the experiment was to let large organic substrates, in this case wood, be colonised by specialised microbes originating from sea water. The idea came from the observation that wood found on the seafloor was often colonized by mats made of sulfur oxidizing microorganisms that were not detected in the surrounding seawater (Kalenitchenko et al., 2015, 2016). These microorganisms belong to the planktonic rare biosphere and become abundant when they encounter a suitable substrate. The study design consisted in a dilution approach. Wood pieces were inoculated with different dilutions of sea water and the presence of key microorganisms involved in the sulfur cycle was analysed after 4 weeks of incubation. Through the classical approach in microbiology called the most probable number (MPN), the cell number of the colonizing organisms was estimated in the original seawater inoculum. Seawater communities were simultaneously described by deep Illumina sequencing. Interestingly, the taxa growing on the wood were identified as marine microorganisms, but they could not be detected in sea water by sequencing. Their abundance was so low that even deep sequencing could not reveal their presence. The MPN approach showed that they had occurrences as low as 1 cell in 10 L of seawater or as little as 0.00000002 % of the cells in the aquaria. It means that theoretically, if PCR or sequencing bias were not considered, one would thus need at least 8,038,282,890 sequences (the number of bacteria present in average in 10 L of seawater) to be able to detect these rare bacterial cells. This estimation exceeds by orders of magnitude earlier numbers. The authors thus proposed an additional category of rare microbes that they named the ultra-rare. The ultra-rare microbes would be defined as microbes that are typically not detected by high throughput sequencing approaches, but that are nevertheless viable and able to colonize new ecosystems with the potential to fulfil an important function in the marine ecosystem (Fig. 2).

The Ecology of the Rare Biosphere

New sequencing technologies have revealed the true extent of microbial diversity in a number of ecosystems. Despite the early debate on the reality of the observed richness, it is now acknowledged that microbial communities in nature are composed mostly of rare taxa. The logical question is therefore why are there so many rare taxa and what do they do? When Pedrós-Alió first reviewed the concept of the rare microbes, he defined them as a seed bank of species that could become abundant when conditions become favourable (Pedrós-Alió, 2006a). The majority of rare microbes that compose the diversity of communities would thus be dormant or slow growing (Jones and Lennon, 2010a), just waiting for an opportunity to wake up and multiply. The first studies dedicated to

Fig. 2 Infographic illustrating the concept of rare and ultra-rare microbes (upper panel) put into human perspective (lower panel). Rare microbes have a frequency of occurrence lower than 1 cell among 10,000 (<0.01%). Ultra-rare microbes may represent only 1 cell among 8 billion. Drawing by Carole Petetin.

the rare biosphere then gave a more detailed picture of what rare microbes are, showing a more complex picture. A study on the biogeography of rare species, i.e., their large scale spatiotemporal distribution, first showed that rare species were not stochastically distributed, but that they rather show distribution patterns similar to those observed in abundant species (Galand et al., 2009). This finding implied that rare species were most likely subjected to ecological processes such as selection, speciation, and extinction. Then, a study used RNA to target the active fraction of the community, and compare it to the entire community described with DNA. Interestingly, this work on marine microbes showed that a significant portion of the rare community was active (Campbell et al., 2011), thus contradicting the idea that rare microbes represented a seed bank of dormant organisms.

A first proposition to categorise rare microorganisms was published in a study on soil microbes that, at the time, was still based on cloning/sequencing methods. The authors were able to produce a large number of clones and thus describe rare species. Due to technological limitation at the time, the scope of the study was restricted to a single sample but it allowed a first classification of rare species into 2 groups (Elshahed et al., 2008). Group I contained non-unique and non-novel members of the rare biosphere that act as a backup system, which is equivalent to the seed bank, and group II comprised rare bacterial taxa with no close relatives within the dominant species. A study on marine Archaea that focused on the seasonal dynamics of communities year after year then went further in separating the rare biosphere into 3 distinct groups (Hugoni et al., 2013). One group contained the rare microorganisms that became abundant at different times within the same ecosystem. The second group contained cells that were uncommon in public databases and not active. The third fraction contained microbes that were always rare but actively growing. Following that later publication and the latest review by Pedrós-Alió (2012), we can thus propose the following groups of rare microbes.

The Local Seed Bank

The local seed bank is composed of cells that are dormant or little active and that are specific to an ecosystem and essential for its functioning during cycling seasonal environmental conditions. They have also been named as the “conditionally rare taxa” (Shade et al., 2014; Fuentes et al., 2016) and are defined as taxa that are typically found in low abundances in one locality, but occasionally become prevalent. For example, in marine ecosystems with strong seasonality, the local seed bank seen in summer contains microorganisms that become abundant in winter. The local seed bank is adapted to certain environmental conditions, blooms when these conditions are optimal, and then moves back to the rare biosphere until next season. This has been observed for bacteria in the Atlantic Ocean (Bay of Biscay) over a 3 years study in which the authors classified microbes as transient or intermittent depending of their occurrence across seasonal samples (Alonso-Sáez et al., 2015). The role of rare populations as seed banks was also highlighted in the Sargasso Sea, where sequences were partitioned based on frequency of detection as frequent and infrequent (Vergin et al., 2013). In the Chesapeake Bay, over half of the bacterial taxa cycled between being abundant and rare over a 3 year period (Campbell et al., 2011). Archaea have also been targeted in rare biosphere studies. In the coastal Mediterranean Sea, the presence of a local archaeal seed bank contributing to the seasonality of communities was also observed (Hugoni et al., 2013). In lakes, the conditionally rare taxa have been shown to become abundant when the epilimnion and hypolimnion thermal layers were forced to mix to mimic the weakening of the stratification observed in autumn and recreate the following winter mixing (Shade et al., 2014). In soils, studies have tested the response of communities to rewetting events that can imitate the seasonal dry and rainy periods found under various climates. The experiment demonstrated that seed bank microbes “resuscitated” and became abundant following precipitation (Aanderud et al., 2015).

Potential New Colonizers

The potential new colonizers consist of aliens to the studied ecosystem and represent a nonlocal seed bank of microbes that are not found under normal conditions but that have a potential for colonisation. They can be identified as a distinct group because they are usually dormant and composed of organisms that are taxonomically and functionally distinct from the ones found in the studied ecosystem (Elshahed et al., 2008; Hugoni et al., 2013). These rare microbes are not the ones that cycle from abundant to rare between seasons. They lay waiting in the ecosystems, or pass through them, until drastic changes in the environment promote their growth, or they simply die. They can respond to disturbances that occur only exceptionally. For example, in aquatic microbial communities, exposure to salinity stress, either increasing or decreasing salinity, transformed community composition. The disturbed communities had changed due to the recruitment of phylotypes present in the rare biosphere of the original community (Sjöstedt et al., 2012). Another example of severe disturbance is pollution. Rare species have been shown to respond to organic pollutant in freshwater mesocosms (Wang et al., 2017), and rare soil bacteria were shown to bloom in response to hydrocarbon pollution (Fuentes et al., 2016). The group of potential colonizers can also represent microbes waiting for a substrate on which to grow, and this is particularly true in aquatic ecosystems. It has been observed on the sea floor, where specialized chemosynthetic communities become extremely abundant on large organic falls (Kalenitchenko et al., 2018a) or at specific features such as hydrothermal vents (Anderson et al., 2015). These microbes originate from the surrounding seawater, but are so rare that they often go undetected (Kalenitchenko et al., 2018b). They can also represent microbes that are found associated in symbiosis with animals such as corals (Ainsworth et al., 2015) or sponges (Taylor et al., 2013). Again, they will be part of the rare marine-water biosphere before they come into contact with the host.

These potential new colonizers may also be on their way to local extinction (Pedrós-Alió, 2012). If they do not encounter a suitable niche or substrate for growth, they could, with time, disappear. If they do not get extinct, they can also become remnants of microbial evolution that, although currently out-competed in all global ecosystems, possess an exceptional ability to survive and escape extinction (Elshahed et al., 2008).

Always Rare but Active

This last group of rare microbes cannot be considered a seed bank because it is composed of active microbes that, in some cases, can show similar taxonomic affiliation and seasonal dynamics compared to the abundant microbes (Hugoni et al., 2013). Several studies have used RNA as a marker for activity in microbial communities. By calculating a ratio of RNA to DNA after amplifying the 16S rRNA gene, one can estimate the level of metabolic activity of an OTU in the environment. There are strong limitations to the approach and the interpretation of the results obtained by targeting RNA are very much discussed (Blazewicz et al., 2013). Nevertheless, the method is used and a study has showed that at least half of the rare bacteria found in coastal waters of the Delaware coast were metabolically active (Campbell et al., 2011), and that many rare archaea were active in the coastal Mediterranean Sea (Hugoni et al., 2013). Similarly, for freshwater ecosystems, a high proportion of rare bacteria were found to be active in lakes (Jones and Lennon, 2010a). Some of these rare active bacteria could carry out major ecological roles. For example, a specific group of rare methane oxidizing bacteria regulated methane emissions from floodplains (Bodelier et al., 2013). In peatland ecosystems, sulfate reduction can be conducted by single genus of bacteria that comprised less than 0.006% of the total microbial community (Pester et al., 2010) or by a consortium of low-abundance bacteria (Hausmann et al., 2016). Analysis of bacterial activity at the single cell scale also showed that rare microbes could play a significant role in the nitrogen and carbon cycles in the environment (Musat et al., 2008).

The intriguing question is why would active microbes that are key players in the ecosystem remain rare. One hypothesis is that by remaining at low abundance, microbes could minimise predation or viral lysis. Both processes depend on prey encounter probabilities, which are lower for rare microbes. This would fit the killing the winner hypothesis that states that the most abundant microbes, the winners, will be exposed to strong predatory pressure (Winter et al., 2010).

What About Protists?

Protists are key components of microbial communities (Caron et al., 2009; Worden et al., 2015), yet, for historical reasons, they have been overlooked in community ecology studies as well as in studies focusing on rare taxa. Protists feature fundamental differences with prokaryotes in terms of cellular structure, feeding habits, diversity of metabolisms, growth rates and behaviour (Massana and Logares, 2013; Keeling and Del Campo, 2017). Therefore, understanding rare prokaryotes does not imply that we understand rare protists. The available studies thus far indicate that protistan communities feature a large number of rare taxa that constitute a “rare biosphere” (Caron and Countway, 2009; Logares et al., 2015). Even though there are no figures as in prokaryotes, we suspect that with the current amount of sequencing we are only sampling the tip of the iceberg of the protistan rare biosphere. Interestingly, Massana and Logares (2013) proposed that the size of the rare protistan biosphere could be smaller than in its prokaryotic counterparts, given that survival mechanisms in protists could be less developed than in prokaryotes. Another reason is that the “delights of a diluted life” (Pedrós-Alió, 2006b), may not be so obvious for protists. Some picoeukaryotes may not be able to escape predation even after reducing their cell size to the minimum (Massana and Logares, 2013). Furthermore, most small protists are naked, the lack of a rigid cell-wall may limit their opportunities for dormancy. In addition, several protist species may engage in sex, which represents a process that helps maintaining the cohesiveness of eukaryotic species. If the chances of finding a sexual partner become extremely low, as it could happen in the rare biosphere, then the advantages of rarity would be reduced among protists. One important difference between the latter groups is that while prokaryotes seem to enter into a dormant state easily and then establish a seed-bank, this behaviour does not seem to be that common in aquatic protists (Massana and Logares, 2013; Logares et al., 2015). Thus, it follows that rare protists are likely metabolically active (Logares et al., 2015). This has been supported by a study in lakes that found a strong coupling between the total number of protists detected (rDNA fraction) and the active protists (rRNA fraction) (Jones and Lennon, 2010b). In contrast, the total and active bacterial communities analysed in the latter study were decoupled. For protists, similar results to those obtained by Jones and Lennon (2010b) were obtained by Logares et al. (2014b) in a study of marine-coastal communities from Europe. There, researchers did not find large deviations in the total and active communities, pointing to metabolic activity in abundant as well as in rare taxa. In sum, aquatic protistan communities also feature a rare biosphere, yet, whether its size is equal or smaller than that of prokaryotes is a matter of debate. What seems to be clear is that protists do not form extensive seed-banks as prokaryotes, and therefore, communities experiencing repeatable changes (e.g., seasonal) probably reconstitute previous states by recruiting metabolically active, yet low-abundance, taxa.

Perspectives

The development of sequencing technologies has revealed the true extent of microbial diversity in all ecosystems on earth, pointing to a never ending long tail of rare microbes. But, as more and more sequences are obtained for each single studied sample, it appears

that we are still not able to describe all the microorganisms found in the environment. Recent publications gave estimates ranging from 2 millions (Crespo et al., 2016) to 8 billions (Kalenitchenko et al., 2018b) sequences needed to fully describe communities in a ca. 10 L of seawater. The wide range of numbers proposed (3 orders of magnitudes) illustrates the difficulty of estimating the true diversity of microbial communities in nature. It also shows that with the sequencing effort routinely used today, from 20,000 to 100,000 sequences per sample, studies only depict the most common members of the rare biosphere.

Two kinds of approaches would be useful in the future to better understand the ecology of the rare biosphere. First, a massive sequencing effort should target samples from different ecosystems to probe the extent of the diversity of communities. For a reliable result, the approach should combine different sets of universal 16S rRNA primers so that microbial diversity would theoretically be covered extensively, and taxonomic blind spots avoided. The DNA extraction method should also be carefully chosen, so that the DNA of most of the microbes present in a sample is released. Finally, the size of the sample, for example volume of water or grams of soils, should be large enough so that it can represent the diversity of an ecosystem. Metagenomic approaches would also be useful as they are thought to be less biased than PCR-based methods. The number of metagenomic sequences required to get a good coverage of the diversity of environmental DNA is, however, very large and probably beyond reach with the existing sequencing technology.

A second approach would rely on culturing. It is well known that strain isolation from environmental samples only recover a small proportion of the organisms. Long referred as the great plate count anomaly (Staley and Konopka, 1985), culturing tends to be biased toward microorganisms that are not common in the environment. This bias can be exploited to get a better insight into the metabolisms of rare microbes (Lynch and Neufeld, 2015). Culturing approaches have already successfully allowed the detection of rare members of the communities in different ecosystems, such as soils (Shade et al., 2012) or deep sea corals (Jensen et al., 2015).

Finally, experimental approaches have proven to be useful tools to promote the growth of rare species. Experiments designed to provoke drastic changes in the environment have always showed members of the rare biosphere becoming abundant and thus being potentially characterized (Sjöstedt et al., 2012; Shade et al., 2014; Kalenitchenko et al., 2018b; Wang et al., 2017). These were often so rare in the original community that they were not detected at all. Such approaches will allow the indirect quantification of rare species and a better understanding of their role in the environment.

Glossary

Biogeochemistry The study of processes and reactions that govern the composition of the natural environment and the cycles of matter and energy that transport the earth's chemical components in time and space.

Eutrophic Enriched with inorganic nutrient resources, such as N or P, to the level that excessive amounts of phototrophic biomass is produced. The term is primarily applied to aquatic ecosystems.

Functional redundancy A property of a microbial community in which different species have the potential to perform the same functional role in an ecosystem. A consequence is that reductions in species diversity may not affect ecosystem functionality.

In situ Located in the natural environmental habitat.

Limiting nutrient A nutrient resource whose concentration or flux rate limits the amount of biomass in the habitat, the growth rate of organisms in the habitat, or both.

Microenvironment The chemical, physical, and biological factors that are located within a few micrometers of the exterior surface of a microbial cell.

Oligotrophic An aquatic ecosystem that has low nutrient resource levels, and as a result, low biomass levels.

Planktonic Free-floating microbiological organisms dispersed in solution within an aquatic habitat.

Subsurface The zone below the surface of the earth. For ocean systems, depths >200 m may be considered the subsurface. In terrestrial systems, sediment at depths below the rooting zone of the plant community may be considered the subsurface.

Thermodynamically favorable reaction A reaction in which the Gibbs free energy in the products is less than in the reactants. That is, the reaction releases energy. These reactions can occur spontaneously, although the reaction rate may be greatly enhanced by a catalyst such as an enzyme.

Abbreviation

DOC	dissolved organic carbon
HGT	horizontal gene transfer
HPK	histidine protein kinase
PCR	polymerase chain reaction
RTFs	resistance transfer factors
SIMS	secondary ion mass spectrometry

Defining Statement

This article provides an overview of the field of microbial ecology by delineating its principles, historical development, areas of study, and experimental approaches.

What is Microbial Ecology?

The term ecology was devised by Ernst Haeckel from the Greek *oekologie* meaning 'the study of the household of nature' in 1866. Hence, microbial ecology concerns the interactions of microbes with both their abiotic and biotic environments. Microorganisms are ubiquitous – they grow not only in soil, freshwater and marine habitats, and on or within plants or animals, but also in so-called extreme environments with chemical and physical conditions that exclude most if not all other forms of life. Thus, the field is extraordinarily broad; a number of other articles in this encyclopedia discuss specific topics within this broad field. This article represents a synthesis of developments that may have arisen from the study of different environments or different organisms, and puts them into a historical context of how microbial ecology has developed and (more importantly) where it may be heading in the future.

This article is an update of A. Konopka, Ecology, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 91-106.

The definition of microbial ecology is very important, because it leads to some important points regarding the discipline. Microorganisms (by definition) are too small to be seen with the naked eye; bacterial, archaeal, fungal, and protistan cells typically have diameters between 1 and 100 μm , with bacterial sizes heavily skewed to the smaller end of this distribution and protists at the larger end. Consequently, the 'environment' that these organisms are sensing must also be at a micron scale (the microenvironment). This scale is far too small for humans to sense directly. We can analyze larger, macroscopic samples and infer what occurs at the microscale, although there is a great risk that the properties we measure in the large sample merely represent the average of a rich heterogeneity at the microscale. Because of this, technological innovations are important to microbial ecology when they allow authentic analysis of the *in situ* environment. The definition of microbial ecology also indicates that the intellectual interests and approaches of the microbial ecologist are quite distinct from those of the laboratory-oriented microbiologist who focuses on analysis of pure cultures of microbes. Microbes in nature interact not only with their abiotic environment but also within biological communities of other microbes and perhaps plants and animals. These complex systems may exhibit behaviors that are not predictable from study of the individual organisms in isolation.

That being said, most microbial ecologists have been trained as laboratory-oriented microbiologists rather than as ecologists; as a result, their understanding of ecological theory is often rudimentary. This can lead to conceptual problems, either because problems in microbial ecology do not become well integrated into ecological theory or because there is no clear recognition where the ecology of microbes has elements that are unique from those of plants or animals.

Historical Development of Microbial Ecology

The realization that there was a microbial world depended upon technological innovation – Anton van Leeuwenhoek improved techniques in lens grinding that led to his visualization of 'animalcules' in the late 1600s. However, the discipline of microbiology did not really develop until the late nineteenth and early twentieth centuries when Louis Pasteur and Robert Koch took on practical problems that arose from the interaction of microbes with their environments (such as the germ theory of disease). Their studies were not ecological, but they did develop technologies for the fundamental manipulation of microbes that are still used today. Also in the early twentieth century, Martinus Beijerinck and Sergei Winogradsky became interested in the activities of microbes in natural habitats. They took into consideration the chemical conditions in the natural environment and devised selective conditions (enrichment cultures) by which they could isolate organisms that carried out specific biogeochemical activities. However, their focus was not on the habitat *per se* but on the physiology of the microorganism, and their studies did not focus on ecological interactions.

Modern microbial ecology had its origins in the 1950s, in the study of the rumen ecosystem by Robert Hungate and his colleagues. Hungate is well known for his development of techniques for the cultivation of strict anaerobes. In addition, he had an interest in quantitative analysis of microbial ecosystems. This followed from his studies with C.B. van Niel on cellulose hydrolysis by gut microbiota first in beetles and termites and subsequently in the bovine rumen. He pioneered studies in which the analysis did not end at the isolation and characterization of pure cultures, but necessarily included the enumeration of organisms in the habitat and quantification of their activities. This quantitative analysis distinguished major from minor microbial species and catabolic pathways in the rumen ecosystem.

As in other areas of science, progress in microbial ecology has been intimately tied to the development of new technologies. The availability of radioisotopes beginning in the 1950s was a major impetus for the measurement of biogeochemical process rates in nature. A major problem is that samples must usually be removed from the habitat and incubated under artificial conditions. As incubation time lengthens, the risk of bottle effects that produce results different from *in situ* rates increases. Thus, there is a premium on sensitive detection methods in which incubation time is minimized. The use of ^{14}C allowed analysis of rates of primary production by phototrophs and chemoautotrophs, and both ^{14}C - and ^3H -isotopic forms of a broad variety of organic compounds have been applied to analyze fundamental processes such as nutrient uptake and assimilation, mineralization to CO_2 , and microbial community growth rates. ^{32}P and ^{35}S isotopes have been applied to measure biogeochemical process rates in the phosphorus and sulfur cycles. Unfortunately, no practically useful N radioisotope is available, although advances in the sensitivity of stable isotope analyses may make ^{15}N analyses at short incubation times feasible. Another significant breakthrough in analysis of microbial process rates came in the 1980s, when microelectrodes sensitive to certain chemical species were developed. These electrodes have a spatial resolution of 50–100 μm , and have produced great insights into the spatial and temporal dynamics of microbial processes in habitats such as microbial mats and sediments.

Quantitative analyses of biogeochemical process rates blossomed in the period after radioisotopes became widely available, but these studies were incomplete because the specific microbial catalysts were not identified. The techniques of pure culture microbiology were broadly recognized to be ineffective in cultivating numerically abundant organisms from nature. However, over the past 25 years, a set of cultivation-independent techniques have evolved to determine the relative abundance of microbes in a habitat. Carl Woese demonstrated that the sequence of the small subunit ribosomal RNA molecule could be used as a molecular chronometer to analyze the phylogenetic relationships among all forms of life. Norm Pace took this seminal idea and applied it to the analysis of 'who's there' in natural environments. That is, by isolation of nucleic acids directly from a natural environment, amplification of small subunit rRNA gene sequences by polymerase chain reaction (PCR), DNA sequencing of the amplicons, and comparison of the retrieved sequences to the ever-growing database of sequences from pure cultures and environmental DNA, it was unnecessary to cultivate the organism to determine their presence. This has become the major activity in the field of microbial ecology over the past 15 years, and has provided tremendous insights into the phylogenetic diversity present within microbial habitats. However, the determination of what microbes are present in a habitat does not directly resolve the problem of specifically

linking specific microbes to their quantitative biogeochemical role in habitats. Metagenomics, the sequencing of total DNA recovered from an environment, now provides insights into biogeochemical potential, but measuring actual expression of that potential remains a difficult technical problem in the discipline.

The Scope of Microbial Ecology

Microbes are present in almost all aquatic and terrestrial environments, and associated with all plant and animal species. Although each of these habitats may have unique aspects that select for particular strategies among microbes, in this general discussion of microbial ecology, the focus will be on elements that are common to different physical habitats.

Microbes' impact at different spatial scales

The biosphere can be construed as a series of interlinked systems that operate at different spatial scales. Microbes physically operate at a micrometer scale, but both impact and are impacted by processes that operate at larger scales. At the largest scales (global and landscape) are aquatic and terrestrial biomes. Biomes are large geographical areas defined by macroecologists on the basis of their distinctive flora and fauna, which presumably reflect selection and adaptation to climate and geography. For example, terrestrial biomes include temperate deciduous forests, grasslands, rainforests, deserts, taiga, and tundra. Marine aquatic biomes would include polar, temperate, and tropical oceans, and freshwater biomes comprise flowing water (rivers and streams), lakes, and ponds, or wetlands. Whereas biogeography (the study of the distribution of organisms over space and time) is well established for plants and animals, the concept has been less intensively studied for microbes until very recently. There are studies in which there is a correlation between geographic distance and genetic distance for specific bacterial groups. In addition, an increase in the number of taxa detected with increases in sampling area has been found for microbes, as has been found many times for plants and animals. However, the underlying mechanisms responsible for the species-area relationship may be quite different in microbes, due to unique mechanisms for phylogenetically broad genetic transfer and (in some cases) high rates of recombination.

At the global and landscape scale, biotic and abiotic planetary processes can impact each other across biomes. For example, oceanic photosynthesis may be limited by the amount of iron; iron is a cofactor for electron transport proteins essential for conversion of solar energy to a biologically useful form of energy. Arid conditions in deserts produce iron-rich dust particles that can be transported thousands of kilometers through the atmosphere and deposited in the ocean. As another example, the global dispersal of animal viruses such as West Nile virus and influenza virus H5N1 can be mediated by migratory birds.

At the ecosystem scale, there are rich, complementary interactions between physical, chemical, and biological components. For example, photosynthetic sulfur bacteria may occur in freshwater lakes; they require light energy, sulfide as an electron donor that will be used in large part to reduce CO_2 to the oxidation level of cell organic matter, and anaerobic conditions. This combination of factors only occurs in lakes where morphometry, nutrient inputs, and biology are constrained within certain limits (Fig. 1).

Fig. 1 System interactions affect the occurrence and intensity of photosynthetic bacteria in lakes. These microbes will only be active at strata where light, anaerobic conditions, and reduced S cooccur. The diagram depicts important physical, chemical, and biological factors, and whether an increase in intensity of one factor produces an increase (+) or decrease (–) in a related factor. For example, increases in inorganic nutrient concentrations stimulate phytoplankton growth. This has a negative effect on water transparency at depth (necessary for photosynthetic bacteria) but also results in a larger flux of organic matter to sediments. This stimulates sulfide production, which is also required for photosynthetic bacterial production. The morphometry of the lake basin and its degree of wind protection drive the intensity of lake mixing, which affects the depth from the sediment to which anaerobiosis can extend. Reproduced from Parkin, T.B., Brock, T.D., 1980. Photosynthetic bacterial production in lakes – the effects of light intensity. *Limnology and Oceanography* 25, 711–718.

Fig. 2 The microenvironment. The volume within a few micrometers from the microbial cell surface has the greatest impact upon it. External resources are transported across the cell membrane via membrane-bound permeases. Microbial cells contain sensors at their cell surfaces that can detect chemical signals in the environment. This can lead to changes in gene expression and alterations in microbial cell activity. Reproduced from Konopka, A., 2006. Microbial ecology – searching for principles. *Microbe* 1, 175–179.

However, to understand the mechanistic basis for interactions of a microbe with its environment, one must consider the conditions within a few microns of the cell surface, the microenvironment (Fig. 2). The cell's surface interacts with the external physical environment – this includes physical factors such as temperature or light but may also involve interactions with the surface of minerals or microbial or metazoan cells. A broad suite of chemicals are present – some are required nutrient resources, but others may be toxic or represent signals arising from other cells. The chemicals may arrive at the cell surface by diffusion from the bulk phase liquid, or via intimate contact in dense biofilms. For nutrient resources, there are membrane-bound permeases that transport molecules into the cell. As single-celled organisms, microbes have evolved a series of sensors on cell surfaces to detect and respond to chemical cues. One such system results in a molecular memory of past chemical concentrations and controls the rotation of bacterial flagella in a way that effects chemotaxis. In N₂-fixing root nodule symbioses, chemical cues are passed between *Rhizobium* species and specific plant legumes; flavonoids excreted from plant roots are the key signals in initiation of nodule formation in the nitrogen-fixing symbiosis. They bind to NodD proteins in the rhizobial cytoplasmic membrane and these sensors also activate transcription of nodulation genes critical for the initiation of root nodule formation. Some of these *nod* genes specify enzymes that synthesize lipochitooligosaccharides, molecules that are sensed by root cell sensors and lead to morphological changes in them. Environmental sensors may also be important in animal pathogenesis. The low pH of the human stomach is a defense mechanism against bacterial infection of the gastrointestinal tract. In the human pathogen *Vibrio cholerae*, however, transcription of genes required for colonization and pathogenesis is induced by exposure to acid and higher temperatures as would occur after a host ingested the organism from the environment.

A phylogenetically widespread regulatory system that can detect environmental signals and produce changes in bacterial gene expression is two-component regulatory systems, in which one component is a histidine protein kinase (HPK). Approximately 5000 have been identified by bioinformatic analysis of more than 200 bacterial genomes. The proportion of the genome that encoded HPKs increased as genome size increased, and many of the organisms with very high proportions of HPK exist in anaerobic sedimentary habitats in which there are steep chemical gradients over short scales (such as δ - and ϵ -proteobacteria) or have relatively complex life cycles (the cyanobacterium *Nostoc* and aquatic chemoheterotroph *Caulobacter crescentus*). On the other hand, bacteria that are intracellular parasites of eukaryotes might be expected to encounter a more constant external environment and they were found to have few HPK genes.

Categorizing microbial ecosystems

A focus on the microscopic scale suggests a set of microbial ecosystems (Table 1), based upon the relevant physical and chemical characteristics at that scale. The quintessential characteristic of aquatic habitats is the planktonic (free-floating) lifestyle. Growth of planktonic chemoheterotrophic bacteria is generally limited by labile, dissolved organic carbon (DOC) present as sugars, amino acids, and organic acids that arise from larger organisms via excretion, lysis, or hydrolysis of macromolecules. The total DOC concentration in ocean waters may approach 1 mg l⁻¹, but this represents a pool of several hundred different organic molecules, each present at very low (nmol l⁻¹ to μ mol l⁻¹) concentrations. The concentrations are low because the bacteria have evolved high-affinity transport systems, and competitive forces select for microbes that can exploit multiple substrates at low concentrations.

Other microbes must deal with strong concentration gradients of chemical substances, because they are relatively fixed in a solid matrix (such as an aquatic sediment, subsurface aquifer, microscopic biofilm, or macroscopic microbial mat). Strong spatial gradients form in these systems because the chemical sources and sinks differ in location. If microbes are sinks or sources for chemical species, their numbers and activity will affect the steepness of the gradients. These gradient systems may be stable in time

Table 1 Microbial-scale ecosystems

Ecosystem type	Examples	Characteristics
Planktonic	Open ocean, lakes	'Oligotroph lifestyle' High affinity for uptake of multiple nutrients
Surface-associated saturated water	Freshwater and ocean sediments, subsurface sediments, microbial mats, biofilms	'Gradient lifestyle' Hydrodynamic processes and fluid flow determine nutrient fluxes Biomass density affects gradient steepness Water availability as limiting factor for activity and dispersal
Surface-associated unsaturated water	Surface and vadose zone soils	Patchy nutrient distribution Dormancy
Macroorganism associated	Gastrointestinal tract, rhizosphere, epiphytes	Coevolution, specific molecular interactions with surface-associated molecules

Reproduced from Konopka, A., 2006. Microbial ecology – searching for principles. *Microbe* 1, 175–179.

Fig. 3 Microbial interactions and dynamics in a microbial mat. The flow diagram illustrates major functional groups of microbes and transformations in the biogeochemical C and S cycles. The depth profiles on the left present idealized gradients of O_2 and H_2S during the day (when photosynthetic oxygen evolution occurs) and at night (when respiratory processes lead to anoxic conditions through much of the mat). Reproduced from DesMarais, D.J., 2003. Biogeochemistry of hypersaline microbial mats illustrates the dynamics of modern microbial ecosystems and the early evolution of the biosphere. *The Biological Bulletin* 204, 160–167.

or show significant temporal fluctuations. For example, microbial mats contain photoautotrophic cyanobacteria in the top few millimeters of the mat and a variety of chemoheterotrophic bacteria are located deeper. Experiments with microelectrodes have shown that there are large and rapid changes in chemical species such as O_2 , H_2S , and H^+ just after the sun rises and after it sets (Fig. 3).

Terrestrial soil habitats that are not saturated with water may be likened to vast deserts in which there is an occasional convergence of water, nutrients, and microbial cells on a particle that results in a burst of microbial activity. Soils may seem to be rich with microbes (10^9 bacterial cells and thousands of different bacterial genomes per gram), but these numbers occupy $<0.01\%$ of the soil volume. The spatial location of microbial activities in soil can be conceptualized as a series of three-dimensional maps that overlay each other within a matrix of pores. These maps describe the spatial location of (1) different microbes (which have distinct biochemical functionalities), (2) chemical resources (organic and inorganic), and (3) water and gases. Each is necessary but none by themselves is sufficient – activity will proceed only where appropriate levels of all necessary factors intersect. The result is a complex three-dimensional landscape in which the physical structure, determined by not only the mineral matrix but also by plant roots, microbial cells, and extrapolymeric substances, sets the conditions for the activity of microbes and the fate of organic and inorganic C, N, and other elements.

In the case of plants or animals as microbial ecosystems, there is an additional dimension to the chemical gradients and physical structure of the ecosystems described above. That is the capacity for very specific molecular interactions with biomolecules on cells of the plant or animal, and the capacity for (co)evolution by both the microbe and its 'environment'.

Thinking like a microbe

Microbial activity at the microscopic system level produces effects at the macroscopic and landscape level. These effects have relevance for scientific disciplines such as macroecology, biogeochemistry, and geology. However, there are principles unique to the

ecology of microbes, and they only emerge from 'thinking like a microbe'; that is, by considering interactions with the environment at the microscopic scale. It is important to keep in mind some characteristics that distinguish microbes from macroorganisms:

- Small size – Optical amplification (microscopy) is an invaluable tool to assess the distribution of microbes in natural habitats.
- Fast rates of growth and metabolism – Per unit biomass, microbes grow and metabolize much more rapidly than macroorganisms. Generation times of 1–2 days in natural environments are not unusual.
- Exponential growth of populations – The growth of individual microbial cells is autocatalytic; a cell grows to form two cells, each of which can catalyze further growth. When coupled with the relatively fast growth rates of microbes, favorable environmental conditions can produce explosive increases in microbial populations over short period of times.
- Rapid dispersal can occur over long distances – Due to their small size, microbes can be carried for long distances by air or water turbulence. In addition, animals may transport bacteria via mechanisms such as fecal transmission.
- Genetic flexibility – Although Bacteria, Archaea, and many fungi lack sexual recombination mechanisms, many microbes possess genetic elements that mediate vectorial gene transfer from donors to recipients. Analysis of microbial genomes shows that gene transfer is not limited to within a species, but may occur across broad phylogenetic boundaries. In the cases of resistance to newly introduced antibiotics and metabolism of novel xenobiotic organic compounds, evolution has occurred over a period of decades rather than millennia.
- Adaptability to environmental extremes – Most microbial species tolerate and grow within what we consider the normal range of environmental factors such as temperature, pH and chemical concentrations. However, species that are optimally adapted to these environmental extremes have evolved.

Principles of Microbial Ecology

A statement of general principles is difficult, because the attention of microbial ecologists is diffused over many different habitats. Thus, there is a tendency to focus on the idiosyncratic rather than the general. In this section, an attempt is made to synthesize phenomena and search for fundamental principles among the unique features of diverse ecosystems.

Overarching Principles

Principle 1. The primary role of microbes in the biosphere is as catalysts of biogeochemical cycles. That is, they mediate kinetically inhibited but thermodynamically favorable reactions. Some microbes may also have strong effects on the ecology of specific micro- or macroorganisms, via their roles as pathogens or symbionts.

Solar energy is the external energy source that drives the biosynthesis of organic matter from inorganic C, N, P, S, and trace elements by photosynthetic primary producers. These inorganic nutrient sources are present in finite amounts; microbes are often largely responsible for catabolism of organic compounds by which the mineral forms used by primary producers are regenerated.

In terrestrial ecosystems, plants are responsible for the great bulk of primary production. Plant organic matter becomes available for microbial decomposition in forms that vary in molecular structure, susceptibility to degradation, and temporal availability. These include root exudates, the fine meshwork of root tissue in soil, and the seasonal fall of plant litter onto the soil surface. Each source may contain complex mixtures of organic substrates that range from low molecular weight sugars, organic acids, and amino acids to macromolecules. Macromolecule catabolism involves initial hydrolysis to monomers by microbial extracellular hydrolases and subsequent intracellular metabolism. Not only is organic carbon oxidized back to CO_2 , but catabolism converts organic N, P, and S to NH_4^+ , PO_4^{3-} , and SO_4^{2-} . In this process, energy is released by breaking C–C covalent bonds; some of the released energy is conserved by microbes and used to drive their growth.

The cycling of organic C in soil intersects with biogeochemical reactions in which inorganic chemical species serve either as terminal electron acceptors or as electron donors. These reactions are particularly important with respect to N, because these transformations affect the bioavailability of inorganic N for plants. For example, NH_4^+ is a reduced form of N that is used as an energy source by nitrifying bacteria, and NO_3^- is the end product of nitrification. However, NO_3^- is more mobile than NH_4^+ in soil solution, and hence more susceptible to loss. Furthermore, if the soil becomes anoxic, NO_3^- can substitute for O_2 as a terminal electron acceptor for chemoheterotrophic microbial metabolism. The oxidized end products, N_2O and N_2 , are gaseous and thus represent a loss of N for plants.

In addition to their biogeochemical function in nature, the specific interaction that microbes have with plants or animals can have major consequences, not only on the affected organisms but also on the ecosystem. Frank pathogens of plants and animals can generate selection pressures to evolve resistance determinants upon their hosts. For example, humans with the sickle cell trait (one allele of an altered form of hemoglobin along with one normal allele) are more likely to survive disease caused by the malaria protozoan parasite than individuals homozygous for normal hemoglobin. The incidence of sickle cell trait in humans is highly correlated with areas in which malaria is endemic.

Microbes can also positively affect macroorganisms via mutualisms. A well-studied example relates to another aspect of the nitrogen biogeochemical cycle. Bacteria such as *Rhizobium* and *Frankia* can form specific associations within nodules on plant roots. These associations make photosynthetically produced organic C available to the microbes. When in association with plants, these microbes express nitrogenase, an enzyme that fixes N_2 into NH_4^+ ; microbial metabolism is regulated such that >90% of fixed N is translocated to the plant.

Principle 2. Although generally unseen to the naked eye, microbes comprise more than 25% of all biomass on Earth. All habitats suitable for plants and animals also harbor microbial populations. In addition, some microbes are adapted to grow under physical and chemical conditions that are too extreme for plant and animal growth.

Determining the amount of microbial biomass on a global scale is difficult to do with precision, but estimates suggest that the amount of organic carbon in Bacteria and Archaea (ca 200 Pg) is approximately one-third of that found in land plants. Estimates of eukaryotic microbial biomass (e.g., fungi in terrestrial habitats) are difficult to obtain, but would certainly augment this estimate significantly. More than half of the biomass on Earth is likely to be microbial. Near-surface terrestrial and aquatic habitats make larger contributions to overall microbial growth and activity. There are few measurements of growth rate in the deep subsurface, but existing measures suggest a generation time for microbes measured in tens to thousands of years; this may reflect occasional periods or locations of microbial growth with most of the microbes surviving in a metabolically quiescent state.

Microbes associated with plants or animals can exert strong ecological effects via parasitism or mutualism. However, in terms of global biomass, these organisms are minor players; they account for less than 1/100,000th of microbial biomass on Earth. Bacteria that function in digestion and nutrition of animal herbivores (ruminants and termites) comprise the largest proportion, due to the large biomass of these animals on Earth.

Humans characterize habitats in which the physical or chemical conditions preclude the existence of plants or animals as 'extreme'. However, some microbes have evolved adaptations in molecular structure such that they are optimally adapted to growth in a particular extreme environment such as very acidic or basic pH, very cold or hot temperatures, or high salt concentrations. These adaptations usually mean that the organisms cannot grow under the conditions we humans consider normal. In the case of thermophiles and psychrophiles, evolution in cellular macromolecules has occurred. For example, cellular enzymes in thermophiles retain structure and activity at higher temperatures; this may be a consequence of more extensive secondary structure and reduced content of certain labile amino acids. A significant problem at low temperature is fluidity of membranes, and the lipids in psychrophiles have increased content of fatty acids that will remain fluid at lower temperatures.

Principle 3. The effects of microbial catalysis (the rates of chemical and energy flow through an ecosystem) depend upon the population size of microbes (the number of catalysts) and their physiological activity (as determined by extant physical and chemical conditions). In stable ecosystems, small numbers of microbes can still produce significant effects over geological time spans.

Microbial population levels and cell-specific activities can range over many orders of magnitude in nature. In aquatic ecosystems such as lakes and coastal marine areas, excessive nutrient enrichment leads to undesirable ecological effects (eutrophication). The amount of P_i loaded into an aquatic ecosystem will often determine the amount of photoautotrophic biomass (Fig. 4) in the water column, and systems with higher levels of photoautotrophic biomass exhibit increased levels of primary productivity. However, physiological studies of phototrophs have shown that the cell-specific rate of photosynthesis will vary significantly as a function of irradiance, and that even at saturating irradiances the photosynthetic rate may vary 5- to 20-fold, depending upon the nature and stringency of nutrient limitation.

The effects of temperature upon activity may be even more striking, when one realizes that much of the biosphere (the deeper waters of oceans and lakes, and many subsurface terrestrial systems) has ambient temperatures of $<10^\circ\text{C}$. As microbes are exposed to temperatures near their minimum, not only do the catalytic rate of enzymes decline, but membrane lipids stiffen, thereby decreasing the effectiveness of membrane-bound transport proteins. As a result, substrate affinity declines and cells are less effective in concentrating substrates from dilute environments. The physiological consequences are that limiting resources can have even more acute effects on activity in cold habitats.

Some processes may occur very slowly, yet have significant impacts on biogeochemical cycles. For example, the anaerobic oxidation of methane in deep-sea sediments is biogeochemically important, given the vast expanse of seabed floor. However, the

Fig. 4 The Vollenweider model of the relationship between the amount of P that enters a lake (P loading in mg P per m³ of lake volume) and the standing crop of phytoplankton biomass (measured as chlorophyll *a*).

process occurs at rates of $\text{nmol cm}^{-3} \text{ year}^{-1}$, and enrichment cultures of the consortium of methanogen and sulfate-reducing bacteria have a doubling time of 7 months, whereas when grown axenically, these organisms double in < 40 hours.

Principle 4. The results of microbial catalysis can have profound effects on the physical and chemical characteristics of the macroenvironment. However, microbial activity is determined by the physical and chemical characteristics of the microenvironment.

There are many habitats in which spatial heterogeneities at the submillimeter scale produce a richer diversity of habitats and niches than is apparent from measurement of bulk average concentrations of chemicals. In the open ocean, there is a spatial mosaic of nanometer-sized organic colloids as well as sheets of organic compounds that may be up to $100 \mu\text{m}$ in size. Aggregation of organic matter and organisms into millimeter-sized particles create a habitat for a rich and diverse community of phytoplankton, protists, and bacteria. In well-aerated soil, local deposition of labile organic matter will create a site of intense activity by aerobic bacteria in which the rate of oxygen consumption exceeds its diffusion and an anoxic microsite in a soil particle can arise.

Strong concentration gradients in environments that result from physico-chemical processes, high densities of active microbes, or (most commonly) the interaction between abiotic and biotic forces also produce strong effects at the microscale. The gastrointestinal tract of insects is a fermentation chamber with a high concentration of microbes; the fermentation products (organic acids) are absorbed through the wall of the gut to fuel the nutrition of the animal. However, O_2 can also diffuse from the trachea across the gut wall, so that much of the gut volume is microoxic rather than fully anaerobic. Furthermore, H_2 is a fermentation product that arises in the anoxic lumen of the gut and is not used by the insect. It is an energy source for aerobic chemoautotrophic bacteria, which have a niche where overlapping gradients of O_2 and H_2 occur in the lumen. In dense microbial mat systems, diurnal changes in light irradiance drive changes in the rate of photosynthetic oxygen evolution that result in rapid temporal changes over millimeter distances in the profiles of O_2 , H_2S , and pH in the mats.

Principle 5. The microbial world exhibits much greater metabolic versatility than is found among macroorganisms. This versatility is exhibited in several different ways:

- Essentially all reduced chemicals found on Earth (both organic and inorganic) can be used as an energy source by some microbe if its oxidation can be coupled to reduction of a terminal electron acceptor in a thermodynamically favorable reaction.

Many biogeochemical cycles operate because some microbe can extract biologically useful energy from the reduced form of an element (e.g., H_2S) and transfer the electrons to a molecule (such as O_2) that has a greater tendency to become reduced (the terminal electron acceptor). The oxidized product (SO_4^{2-}) can then be reduced to H_2S when it serves as a terminal electron acceptor for a different physiological group of microbes.

For organic compounds, all naturally occurring organic compounds and most synthetic organic chemicals can be used as energy sources by microbes. It is easier to list the recalcitrant exceptions – lignin (under anaerobic conditions), highly halogenated organic compounds (under aerobic conditions), branched alkanes, and insoluble synthetic polymers (e.g., polyethylene).

- Individual organisms may be capable of metabolizing a broad range of different substrates.

From an ecological perspective, much of the organic matter that becomes available to chemoheterotrophic bacteria arises via cell lysis from the death of other organisms (plants, animals, or other microbes). The enzymatic hydrolysis of cell macromolecules will produce a rich mixture of various sugars, amino acids, and organic acids. Thus, it is not surprising that individual microbes may possess transporters and enzymes that provide the potential for utilization of many components of these mixtures.

The study of biodegradative enzymes in bacteria has provided insights into some mechanisms whereby a broad substrate utilization range may arise. In some cases, a key enzyme with a broad substrate range has evolved. A halidohydrolase from an *Arthrobacter* sp. is active against more than 50 different halogenated organic compounds that differed in their halogen substituent and ranged from aromatic to saturated or unsaturated alkanes. The evolution of biodegradative metabolic pathways has also made it facile for an organism to utilize multiple organic substrates. There are a large diversity of substituted aromatic compounds that can be aerobically catabolized by microbes. Catabolic pathways entail the action of enzymes that funnel different substrates to one of a few common intermediates (usually dihydroxy benzene derivatives), which are then further catabolized by a common set of enzymes. Thus, the growth substrate range can be augmented by acquisition of enzymes to process specific substrates, once it possesses a core aromatic catabolism pathway.

- Complex microbial communities may be metabolically redundant and contain a number of different populations that can metabolize the same substrate. This metabolic diversity increases resiliency to environmental perturbations, as extreme conditions are less likely to kill all species performing a particular ecological function.

A critical issue in all areas of ecology is to understand the relationship between biodiversity and the functioning and stability of ecosystems. Imagine an ecosystem that is devoid of microbes, and that different species are introduced one by one. Initially, each new species is likely to add a new function to the ecosystem, because it can utilize substrates that the previous species could not. At some point, however, new species are likely to be redundant – an existing species can already carry out that function. The ecosystem possesses its maximum microbial functionality. However, higher biodiversity (with its associated functional redundancy) is valuable if the ecosystem is exposed to changes in environmental conditions such as a change in pH or addition of a toxic metal. If functional redundancy were low, then all species that can carry out a particular function might be eliminated. At higher functional redundancy the probability that at least one species is tolerant of the new environmental condition is higher and the ecosystem then retains this function and is perceived as functionally stable.

- Microbial populations are capable of rapid evolutionary responses to environmental perturbations; this is due to mechanisms that generate relatively high mutation frequencies and a capacity for horizontal gene transfer (HGT) across large phylogenetic boundaries.

Evolution via differential reproduction under environmental selection pressures was the central premise of Darwin's work. In the case of plant and animal species, genetic variation (the raw material upon which selection acts) is generated within one species via the shuffling of genes during sexual reproduction. In microbes, however, there are mechanisms of HGT that can cross broad phylogenetic boundaries and generate completely novel gene combinations in much shorter time frames.

Humans have performed two great natural experiments that illustrate this point – the large-scale introductions of antibiotics and xenobiotic organic compounds. Antibiotic-resistant forms of a pathogen have often arisen within 10–30 years after introduction of a new antibiotic. The acquisition of multiple antibiotic resistance by clinical isolates is conferred by resistance transfer factors (RTFs), broad host range plasmids that contain a set of transposons, each of which has a gene for resistance to a different antibiotic. From where did these plasmids arise? A set of clinical isolates of Enterobacteriaceae that had been archived in the preantibiotic era was found to contain plasmids, and their core genes for replication, maintenance, and conjugal transfer were similar to those found in modern RTFs. However, they did not contain transposons with antibiotic resistance determinants. The implication of these findings is that the use of antibiotics in clinical practice and agriculture results in a strong selection pressure for cells with RTFs in which the appropriate transposon has integrated.

Why can microbial evolution proceed more quickly than in the case of macroorganisms? Microbial generation times can be comparatively short, and each replication of genetic material will result in a small number of mutations. When one considers the total population size of microbial cells in habitats (millions to billions per gram), there are ample opportunities for genetic variation to arise.

The 'evolution' of specific taxa is particularly enhanced by bacterial mechanisms of gene transfer (the uptake of naked DNA by a cell, or transfer of DNA into a recipient bacterium by direct contact with a donor bacterium or infection with a bacterial virus) that may permit horizontal transfer of genetic material across broad phylogenetic barriers. Gene transfer frequencies are directly proportional to cell density – crowded habitats such as animal gastrointestinal tracts, soil microcolonies, the plant rhizosphere, biofilms, and marine snow probably represent important foci. In some instances, the acquisition of a single gene (e.g., an antibiotic resistance gene or exotoxin genes within prophage of *Corynebacterium diphtheriae* or *Clostridium botulinum*) can substantively alter the organism's ecological properties. In other instances, there are functional modules of multiple genes that confer novel properties. Some examples include sets of genes for organic catabolism or pathogenicity islands that contain virulence genes.

Principles in Population Ecology

Principle 6. The types and numbers of different microbes present in a habitat are a function of the diversity and amounts of nutrient resources available; in ecology, this is termed bottom-up control. However, the abundance of a microbe will also be modulated by its ability to withstand forces that eliminate it from the habitat. These loss forces may be biotic (due to the activity of predators and parasites and termed top-down control), physical (flushing or scouring action), or physiological (nutrient starvation).

The effect of nutrient resources upon microbial activity and growth will be discussed below in the context of physiological ecology. Although much of the historical effort in microbial ecology has been directed to the study of bottom-up control, there have been significant studies since the 1980s on the effects that biotic loss factors may have on structuring microbial communities. The recognition of the role played by eukaryotic protists in biogeochemical cycling in the ocean was important in this regard. Bacteria have been found to utilize up to 50% of the carbon fixed by photosynthesis in the ocean. The 'microbial loop' (Fig. 5) provides a means for these resources to be reintroduced into the traditional food chain (via zooplankton to fish). Bacterial numbers are controlled by nanoflagellates and to a lesser degree small ciliated protists, which in turn are preyed upon by microzooplankton. As these predators are of similar size to phytoplankton, they can be consumed by zooplankton and the resources reenter the planktonic food chain. Detailed investigation of other habitats has shown that bacterivorous protists are important in a range of ecosystems, including soil.

There is a vigorous debate between those who contend that bottom-up mechanisms control microbial biomass levels and those who emphasize top-down control. The truth likely lies in the middle, and may differ depending upon season and ecosystem

Fig. 5 The microbial loop in aquatic food chains. Filter feeding by protists upon bacteria can result in the return of primary production back to the classical food chain, as the protists are preyed upon by zooplankton. POM, particulate organic matter; DOM, dissolved organic matter.

productivity. Both empirical and theoretical evidence suggest that bacterial numbers may be more tightly controlled by protistan predation in nutrient-poor (oligotrophic) ecosystems, whereas in nutrient-rich habitats competition for nutrients has primacy. Intuition might lead one to the opposite inference, but eutrophic habitats will have higher population levels of higher-level predators (zooplankton and fish) that keep tighter control on the abundance of bacterivorous protists. As a result, predation pressure on bacteria is reduced and higher bacterial numbers result in more stringent nutrient limitation.

Protistan grazing not only can control bacterial numbers, it can also shape bacterial community composition. Protists employ either filter or interception feeding. As a result, bacterial cells with diameters of 1–3 μm are most susceptible to predation. And, therefore, aquatic protists are very effective predators on rapidly growing single-celled bacteria. Thus, there will be strong selective pressure for antipredator strategies in bacteria that result in smaller or larger particles. Strategies that yield larger particles include morphological changes such as filament formation or production of exopolymers to produce cell aggregates. Ultramicrobacteria (those with a cell diameter of 0.3 μm or less) can be isolated from natural marine samples; these organisms are sized below the optimal feeding range of protists. Chemical defenses have also been found – the purple pigment of *Chromobacterium violaceum* has been found to induce apoptosis in flagellates when a bacterial cell is ingested.

Over the past 25 years, aquatic ecologists have come to recognize that viruses are also significant causes of microbial mortality. There are approximately 10^8 virus particles per milliliter in productive, coastal marine waters. There is significant genetic diversity among these viral particles, and within that diversity are viruses that can infect algae, bacteria, or protists. It has been technically challenging to accurately measure the proportion of microbes that are lysed by viruses; current estimates range from 10% to 50% of the bacterial population per day and the impact of viruses as a loss factor for bacterial production may equal that of bacterivorous protists in marine systems.

Principle 7. Microbial populations and communities often exhibit much larger dynamics in biomass, composition, and activity than do plant and animal populations.

These complex, nonequilibrium dynamics are thought to be primarily driven by the temporal frequency of changes in important environmental factors (and hence, changes in selective environmental forces). An obvious example is a tidal salt marsh, but there are periodicities that exist at shorter and longer frequencies to which microbes can respond. Temporal changes can occur over very different spatial scales, from kilometers in coastal marine upwellings to millimeters in laminated microbial mats. In addition to these environmentally driven changes, there are also internal biological cycles in ecosystems that alter selective forces. Predator–prey cycles are perhaps the best known, but the identification of cross-species molecular signaling in the laboratory suggests that population dynamics may have a larger biological component than we have appreciated.

Microbes respond more dynamically to these changes than macroorganisms as a consequence of their biological properties: a rapid pace of physiological adaptation to changing environmental conditions, a broad variety of positive and negative interactions between different microbes and the capacity for rapid genetic change. An important consequence of principles 6 and 7 is that the observed temporal changes in microbial populations (whether termed ‘community dynamics’, ‘successions’, or ‘oscillations’) are not solely determined by environmental or biological factors, but rather by an intricate interaction among these factors.

Principles in Physiological Ecology

Microbial physiological ecology is a field in which the molecular details of gene regulation can be evaluated in the context of ecological effects under the selective pressures experienced by microbes in nature.

Principle 8. The amount of one essential limiting resource is most likely to determine the amount of microbial biomass in an ecosystem.

A nutrient resource that is taken up may be (1) conserved in functional or structural molecules (i.e., become biomass), (2) utilized and excreted for bioenergetic purposes (energy source and terminal electron acceptor), or (3) function both as a component of biomass and in bioenergetics. All organisms must acquire an energy source (light of the appropriate wavelengths for phototrophs and a reduced chemical for chemotrophs) and the appropriate molecular form of atoms that comprise biomass. The most important atoms are C, N, P, S, and several metals (Fe is often the most quantitatively important) that serve as enzyme cofactors. Chemotrophic bacteria also require a terminal electron acceptor, a molecule to which electrons are ultimately donated after oxidation of the energy source. Autotrophs require reducing power to reduce CO_2 ; in photoautotrophs an external electron donor is used for this purpose via photosynthesis whereas chemoautotrophs may use their reduced energy source directly or generate reductant via reverse electron transport.

The molecules that comprise this elementary set of requirements can be called ‘complementary substrates’ in that all are necessary, but none by themselves are sufficient for growth. However, within each requirement, there may be substitutable forms. All microbes use NH_4^+ as an N source, a number can use NO_3^- , and some fix N_2 . There are hundreds of different organic substrates in the environment; if a specific microbe has uptake systems and enzymes to catabolize them, these represent substitutable substrates.

The limiting nutrient is not necessarily the one present in the lowest absolute concentration in the habitat. Rather, it is the resource in scarcest supply relative to its requirement for biomass synthesis (Liebig’s law of the minimum). It is important to recognize that cellular composition is not immutable. Despite the general biochemical similarity of all organisms, some taxa may have unique requirements. For example, diatoms require silica for their extracellular frustules whereas other groups of phytoplankton do not have this requirement. In addition, physiological conditions may substantially affect the elemental stoichiometry of biomass. Iron is required in a variety of electron transfer proteins such as cytochromes and nonheme iron proteins; it usually

comprises 0.2% or less of a bacterium's dry weight. However, in N-limited environments where N_2 -fixing bacteria would have a selective advantage, the synthesis of Fe-rich nitrogenase and ferredoxin would increase cellular iron content by at least fivefold.

Principle 9. Growth of microbes on the limiting nutrient (or a set of substitutable nutrients) will depress its concentration to a value that limits microbial growth rate. The nutrient flux rate in an ecosystem may become physically limited by hydrodynamics or mass transport.

The 'limiting nutrient' in a habitat has two distinguishable effects on microbial growth. It limits the total amount of biomass. If microbes are inoculated into a sterile environment, they will grow at their maximum rate and at some point the total demand of biomass for nutrient uptake exceeds its supply rate, and the concentration of limiting nutrient decreases. At some low concentration (in the nmol l^{-1} to low $\mu\text{mol l}^{-1}$ range), transport rate into the cell is determined by this low extracellular substrate concentration and a reduced intracellular flux produces a reduced growth rate.

Principle 10. Competition among microbes for low concentrations of limiting substrate and temporal variability in nutrient availability is a strong selective force in natural habitats. A variety of physiological and morphological adaptations can have adaptive value under specific conditions.

1. The number, diversity, and affinity of transporters in the cell membrane: Nutrient concentrations in the nmol to low $\mu\text{mol l}^{-1}$ range are likely to constrain the growth rate. The organisms that can maximize nutrient flux into the cytoplasm will have the highest growth rate and therefore a competitive advantage. In the case of chemoheterotrophic bacteria in the open ocean, organic substrates are likely to be the limiting nutrient. The dissolved organic C level in seawater totals $\sim 1 \text{ mg C l}^{-1}$, but this represents nmol l^{-1} concentrations of a wide variety of specific substrates derived from the lysis of phytoplankton cells and the hydrolysis of their macromolecules. One physiological strategy would be to express genes for high-affinity transporters, because at these low external substrate concentrations, the specific affinity (the initial slope of the uptake rate vs. substrate concentration function) provides a competitive advantage. Furthermore, derepression of gene expression to increase the number of transporters inserted in the membrane will enhance substrate flux via the law of mass action. The maximum rate of transport (V_{max}) normalized to a per cell basis is a function of the number of transporters per cell. Increases in V_{max} not only provide a higher transport rates at saturating substrate concentrations, but also increase flux rates at rate-limiting concentrations (Fig. 6).

When there are approximately 1500 transporters of one specific type in the membrane, they compete with each other for substrate molecules, and further investment in additional transporters of this type is not productive. However, only 2% of the membrane surface is covered with transporters; synthesizing transporters with many different specificities will maximize the total flux of limiting organic C into the cell, if other organic substrates are available. Thus, organic C-limited chemoheterotrophs are predicted to express the capacity for the transport and catabolism of multiple organic substrates. They need only generate a fraction of their total growth rate from the transport flux of each individual organic compound.

2. Regulation of the capacity for substrate uptake versus substrate assimilation: The capacity for nutrient uptake is maximized by increasing the number, diversity, and specific affinity of transporters. However, in a competitive environment this will push ambient substrate concentrations to values where the growth rate is far below maximal. The optimal use of resources under these conditions will regulate decreased amounts of the macromolecular machinery for biosynthesis and assimilation. The most obvious example of this is the direct relationship between growth rate and cellular ribosome content. Ribosomes are energetically expensive to produce; a cellular content that exceeds the required rate of protein synthesis is energetically inefficient.
3. Cell size: When bacteria are grown in a chemostat at a variety of growth rates, slow-growing cells have a smaller size and volume than fast-growing populations. The direct physical reason for this may be the differences in ribosome content mentioned above. A tenfold increase in cellular ribosome content can only be accommodated by increasing the volume of a cell. Direct microscopic

Fig. 6 The effect of increasing the number of membrane-bound permeases per cell, at both low, transport-limiting external substrate concentrations and saturating concentrations. Calculations were made employing the Michaelis–Menten equation at K_s of $10 \mu\text{mol l}^{-1}$, and different V_{max} values. V_{max} is proportional to the number of permeases per cell.

examination of bacteria in aquatic environments indicates that many cells are quite small, with diameters of 0.5 μm . Size-selective predation by protists may play a role here, but the low growth rates typically found in planktonic aquatic ecosystems (doubling times are often measured in the range of 16–50 h) also lead to small cells. The physical nature of small cells has another beneficial effect for nutrient-limited habitats – the surface-to-volume ratio increases as cell diameter decreases. Membrane-bound surface area is the location of substrate transporters, whereas the cytoplasmic volume contains soluble biosynthetic machinery. Thus, decreases in cell size found when nutrient-limited growth is slow have the consequence of increasing the ratio of transporters-to-assimilation machinery.

4. Storage polymers: The physiological responses to nutrient limitation in nature include derepression of nutrient transport systems and downregulation of biosynthetic pathways. However, a microbe may be exposed to pulses of higher nutrient concentration either on a regular diurnal cycle or at irregular intervals (e.g., by encountering particulate organic matter in an aquatic ecosystem). At this physiological state, transport of the limiting nutrient occurs at a much faster rate than can be assimilated into proteins and nucleic acids. The solution to this mismatch is intracellular storage as a polymer that can be assimilated later when external substrate concentration is again limiting.

Storage polymers of C and energy include glycogen, starch, and polyhydroxyalkanoates. P is stored as polyphosphate by a number of microbes. N is the macronutrient for which there is no storage polymer, with the exception of cyanophycin produced in many cyanobacteria and a few heterotrophic bacteria. The polymer consists of an aspartic acid backbone to which arginine residues are linked.

The synthesis and degradation of glycogen by the cyanobacterium *Oscillatoria agardii* during a diurnal light–dark cycle illustrates the interplay between resource acquisition, storage, and cell growth. During the light period, fixed CO_2 is used for immediate growth (synthesis of proteins and nucleic acids) and stored as glycogen. Of particular note is that growth rate (measured as rate of protein synthesis) during the light period is lower than in cells cultured in continuous light. However, during the dark period the intracellularly stored glycogen is used as both a carbon and an energy source – the rate of protein synthesis in the dark is very similar to that measured in the light. That is, the microbes grow chemoheterotrophically in the dark on stored glycogen. This physiological strategy produces a higher daily growth rate than if the cyanobacteria had a growth rate of μ_{max} in the light and 0 in the dark.

Strategic Approaches to the Study of Microbial Ecology

An examination of articles published in microbial ecology journals will illustrate not only the breadth of habitats that are studied by microbial ecologists, but also a variety of technical approaches. Some of the major categories are described below.

Descriptive Studies of the Distribution and Activity of Microbes in a Natural Habitat

‘Descriptive studies’ has become a pejorative term in science, but this type of analysis is a necessary first step when initiating a study on a new habitat. In addition, field studies have an overhead not found in well-controlled laboratory studies – the collection of routine data on physical, chemical, and biological characteristics of the system. It is essential to monitor the natural variation that lies behind any hypothesis-driven field experiments. These routine data can be mined using statistical techniques to uncover relationships between environmental factors and biological activities. These relationships suggest hypotheses that can be experimentally tested.

The most common types of descriptive data published in ecological studies are lists of microbial community members identified from sequences of 16S rRNA gene amplicons or metagenomic analyses. About 23% of the 22,000 papers published on microbial ecology over the past 10 years have included at least one of these data types. Although knowledge of community composition on its own is useful, it is far more impactful to conduct deeper analysis of datasets comprising hundreds of samples. By employing statistical frameworks, changes in microbial community composition in space or time can be used to infer the relative importance of ecological forces (dispersal, selection, and drift) that shape microbial composition. Furthermore, when related to field-scale measurements of physical and chemical variations, the effects of environmental variable variation upon the intensity of those ecological forces can be mapped.

Analysis of *In Situ* Rates of Growth or Biogeochemical Activity

These analyses can rarely be accomplished under true *in situ* conditions, as they entail addition of chemical tracers or measurement of changes in biomass. Thus, natural samples are collected and confined in containers, but incubated under the physical conditions found *in situ*. The removal of a sample from the open conditions of the natural system to a confined bottle will lead to changes with time. Therefore, it is advantageous to keep the incubation time as short as possible. The use of radiotracers (i.e., the addition of a radioactive molecule in an amount that is small enough to have a negligible impact on *in situ* chemical concentration) has been invaluable in rate measurements of biogeochemical processes. Bacterial growth rates have been estimated by measuring the rate at which radioisotopic forms of biosynthetic precursors (such as thymidine or leucine) are incorporated into cellular macromolecules. These calculations require several assumptions, and give an ‘average’ growth rate for a heterogeneous population of microbes.

These results generally suggest that the doubling times of aquatic bacterioplankton are in the range of 1–2 days, much longer than what is achievable with pure cultures in the laboratory. *In situ* growth rate is a fundamental parameter of interest in ecological studies, but it remains a difficult one to accurately and conveniently measure for microbial populations in nature.

Experimental Manipulation of Natural Samples Under Simulated Conditions (Microcosms)

The intent of microcosm experiments is generally not to accurately measure *in situ* activity rates, but rather to perform experimental manipulations of natural microbial communities to test hypotheses regarding the effects of environmental perturbations upon microbial community activity or composition. Incubation times are likely to be much longer than when measuring *in situ* activity rates; therefore, caution in interpretation is warranted as confinement of the sample can introduce major effects.

An example study examined the population structure and activity of a microbial community in soils that were cocontaminated with lead, chromium, and aromatic hydrocarbons. It was difficult to separate the effects of different contaminants by direct analysis of spatial differences in community composition and environmental contaminants. Therefore, microcosm studies were set up in which soil samples from both contaminated and uncontaminated sites were challenged with different terminal electron acceptors and a graded series of heavy metal concentrations, to analyze the effects upon microbial activity (the mineralization of organic carbon) and community composition. The experiments illustrated that if one wanted to detect changes in community composition, it was important to add an energy source (organic substrate) that could drive significant changes in composition. Of course, this energy source will itself represent a strong selective force in structuring the microbial community. However, by comparison of sample treatments, it was possible to demonstrate that whereas resource factors such as the organic energy source and terminal electron acceptor were a major force in structuring species richness, the effects were modulated by toxic factors such as heavy metals. In addition, the factorial design of the experiments (in which a series of combinations of energy sources, terminal electron acceptors, and heavy metal concentrations were tested) showed that microbial activities carried out by a diverse group of functionally redundant community members were more resistant to high toxic metal inputs than activities for which a more restricted diversity of microbes was likely to be present.

Model Laboratory Systems

A distinction between microcosm experiments and model laboratory systems is that the former are initiated with many of the physical and chemical characteristics as well as the taxon richness of the original habitat whereas the latter is often a highly simplified version of nature. In many cases, it may be the study of a pure culture in the laboratory. This can be controversial in microbial ecology, because the laboratory system will lack a large number of features found in nature. However, ecophysiological studies in the laboratory provide the means to rigorously ascertain the physiological responses made by a microbe to environmental changes. These can be approached with a degree of experimental control and replication that is not possible in the habitat. If the study remains housed entirely in the laboratory, it probably ceases to be an ecological one. However, there are advantages to integration of field and laboratory studies, and recursion between real-world complexity and the experimental control that can be applied in the laboratory.

Ecological studies on planktonic cyanobacteria have provided an example of the value of this type of recursion. In eutrophic lakes, cyanobacteria proliferate to high cell densities (blooms) in which >90% of the biomass in the sample consists of one morphological type of cyanobacterium. Under these unique conditions, one can measure physiological properties in whole samples (photosynthetic rate, allocation of fixed C to different macromolecules, rates of macronutrient uptake) and reasonably ascribe these properties to the dominant biomass component. From these measurements on field populations, hypotheses arise regarding the regulatory responses made by the organism to limiting environmental factors. These hypotheses are testable in the laboratory by experiments with cyanobacterial isolates cultivated in chemostats under control of growth rate and stringency of nutrient limitation. As deeper insights are gained into the details of ecophysiological responses from laboratory experiments, it is important to revisit the field and ascertain that those details actually operate under field conditions. This iteration between laboratory and field is straightforward when the natural population has a high relative abundance of the organism of interest. A remaining challenge for microbial ecology is to develop technologies that allow application of this iterative approach to community members present at low relative abundance. This requires the capacity to rapidly detect specific taxa and make physiological measurements on single cells.

Future of Microbial Ecology

The Microbiome

There has been an explosion in the past ten years of work on the ‘microbiome,’ the microbial community in a specific habitat. As often occurs in science, explosions are driven by technology developments – in this case, fast and cheap high-throughput DNA sequencing coupled with bioinformatics algorithms, databases, and methods of data analysis. Currently, the most common approaches after isolating DNA directly from environmental samples are PCR amplicon sequencing of a portion of the 16S rRNA gene and shotgun metagenomic sequencing. These methods have produced tremendous insights into the diversity of microbes and their functional genes, and will continue to be a major component of microbial ecology research in the future. However, these

molecular approaches have not yet reached the aspirations held for them to unlock deeper insights into microbial ecology. The issues include:

1. DNA sequence information provides insight into metabolic potential, but not actual activity. For example, a high proportion of *nif* genes in a metagenome does not indicate that nitrogen fixation actually occurs in the habitat. The dominant biota may have been selected for other traits, but happen to also possess *nif* genes. Advances in the practicality of metatranscriptome and metaproteome analyses would address this gap.
2. Most studies do not conduct adequate sample replication in site, space, or time to derive statistically rigorous conclusions.
3. Hypothesis testing typically involves multivariate statistical analysis of molecular sequence and environmental data. However, these approaches can only indicate correlation but never prove causation.
4. The technical choices for DNA isolation method, primers, and sequencing technology all introduce biases. Hence, comparisons across laboratories and historical studies is difficult. The Earth Microbiome Project is attempting to introduce standards for these issues.
5. Reference databases are inadequate. There is a bias in databases (both for taxa and genes) towards certain relatively well-understood phyla (for example, the Proteobacteria). As a result:
 - a. The commonly used 97% sequence similarity threshold for delineating "taxa" from 16S rRNA sequences probably blurs or does not capture the breadth of microbial ecological heterogeneity.
 - b. In terms of inferring potential microbial physiology from metagenomes, the inadequacies of reference databases mean (a) some annotations are wrong, (b) gene calls are conservative, hence 30–50% of genes found are of undetermined function, and many others identify a protein family rather than a specific enzymatic activity, (c) only environmental genes with >40% identity to a homologous database sequence are very likely to share functional similarity.

Microbiology at the Microscale

It is a central principle that the direct interaction of microbes with their environment occurs at a spatial scale of micrometers. Thus, analysis of the authentic ecology of microbes is enhanced by technologies that increase the spatial resolution of experimental measurements. This applies not only to analysis of the physical and chemical environment around a cell, but also to measuring the physiological and genetic properties of a set of individual microbial cells. In addition, analysis of a set of individual microbial cells can provide the basis to understand not only physiological responses at the microscale, but also the distribution of properties among a population of cells within a natural habitat.

Future possibilities include the continued development of microfluidic devices that can be designed to impose gradients of environmental factors or simulate natural microhabitats (e.g., soil pore network or gastrointestinal villi). Optical sensors for important metabolic reactant (such as O₂ and CO₂) can be incorporated into such devices.

To achieve microscale microbiology, the development and application of high-resolution imaging approaches that couple biochemical analyses to micron scale interactions of microbes with each other and their environment is critical. There have been impressive advances using a variety of approaches in analytical chemistry. These include label-free techniques such as Raman and FTIR microspectroscopy which have been applied to the analysis of microbial cells, and nuclear magnetic resonance that can be used to image biofilms and also provide information on chemical gradients within them. New fluorescence probes and optical imaging systems provide the capacity to interrogate physiological state, gene expression, and phylogenetic identity of individual cells in a natural sample.

Radioisotopes have been a powerful technology in advancing microbial ecology; however, they also have practical limitations for performing *in situ* experiments and handling waste. Stable isotope methodologies have the potential to revolutionize the field of microbial ecology. Sophisticated improvements in nuclear magnetic resonance, mass spectrometry, and Raman spectroscopy are approaching the point that allow the kinetics of metabolic function in microbial communities to be determined with great sensitivity. In contrast to radioisotope-based techniques, stable isotopes provide a means to specifically isolate cellular macromolecules that have incorporated the label and therefore have a unique signature. There remains great scope for technical refinements and advancements in the use of stable isotopes for metabolic and molecular analyses of microbial communities; these future methodological innovations will provide the means to mechanistically understand *in situ* function of microbial communities in a quantitative way. With technology developments regarding sensitivity and spatial resolution, this has the potential to provide a direct link between measurements of community function (metabolism) and expression of functional genes (via labeling and analysis of either mRNA or protein). An example of this has been the application of nanoSIMS (secondary ion mass spectrometry) in microbial ecology, which makes possible the determination of chemical and stable isotope composition at the submicron level.

Single-cell microbial genomics is now a reality, but remains tedious due to current sequencing technologies. If accurate single molecule DNA sequencing comes to fruition, imagine that 300 individual microbes from a habitat are physically separated, and each are subjected to single-molecule genome sequencing. One has in hand a community metagenome in which environmental sequences are inherently placed in their genomic context, and information on the relative abundance of different genomes (and genetic microdiversity within a specific clade) is directly available.

Theory in Microbial Ecology

Technology is not enough. New technologies will generate a blizzard of data at an ever-increasing rate, but understanding can only come from a synthesis of that information. Data-rich technologies carry the risk that they drive science to idiosyncratic pathways

that do not yield deep understanding of fundamental principles. The antidote is to ground studies to sound theory, a synthesis of how we imagine microbial populations and communities operate. In comparison to the ecology of plants and animals, microbial systems are much more experimentally tractable, which provides the opportunity to test theoretical syntheses that are either unique to microbial ecology or derived from the rich body of macroorganismal ecological theory.

There are several means to articulate a theoretical synthesis; a simulation model is one of them. This approach has the virtue of forcing a qualitative, descriptive discipline to become a quantitative, predictive one. The challenges are great, particularly at the community level, because functional redundancy will make precise, unambiguous prediction of community composition uncertain. However, robust model predictions may hold at the cellular, population, and ecosystem levels and lead to deeper insights into principles of microbial ecology than presented here. The greatest value of a simulation modeling approach is an iterative interaction with experimentation. The test of a simple model against ecological reality illuminates its weaknesses, and aspects in which greater depth of detail is necessary. Sensitivity analyses of a refined model suggest the most insightful experiments to carry out in the field, which lead to another round of model refinement.

Does Cultivation Have a Place?

For more than 30 years, the conventional wisdom in microbial ecology is that less than 1% of bacteria in nature can be cultivated. That observation in fact was a driving force for the development of cultivation-independent analyses of nucleic acids that are now the driving force in the field. Does there remain a role for cultivation?

There have been important innovations that can in many cases raise the proportion of cultivatable microbes from a habitat to 10%–25%. Culture chambers that mimic natural environments (for example, by using microfluidic devices) have been successful. Co-culturing has also been effective. Techniques that employ substrate concentrations at *in situ* levels or the addition of substances such as signaling molecules or resuscitation factors have been successful in cultivating relatively high proportions of the population. However, it is true that cultivation remains a time-consuming undertaking that is resists automation.

But cultivation still plays two important roles in microbial ecology, that complement molecular analyses of the microbiome. First, it provides the raw material to improve the genome reference databases that metagenomics relies upon. Secondly, the future entails understanding the functional potential of individual microbial ecotypes (metabolic versatility) as well as functional redundancy in microbial communities, and here molecular approaches have fundamental weaknesses. In particular, metagenomic approaches can uncover novel gene sequences or identify familiar ones, but in the end only allow the formulation of hypotheses that still must be subjected to biochemical analysis for rigorous proof. In contrast, propagation of an isolate under controlled conditions permits application of a broad array of tools to investigate its specific ecophysiology and genetics.

Glossary

Emerging infectious disease(s) Infections that are newly recognized in a population or have existed previously but are rapidly increasing in incidence or geographic range.

One health An interdisciplinary approach that brings together human, animal, and environmental health professionals to address complex global health problems.

Urban sprawl The uncontrolled movement of urban development away from a city central.

Vector Any organism, though usually an arthropod, that can transmit an infectious agent to a host.

Zoonoses Diseases that can be transmitted from an animal to human or a human to animal.

Introduction

Throughout history, infectious diseases have vastly impacted human civilization. This impact has been demonstrated by the relentless appearance of various infectious disease outbreaks, including plague that scourged Europe during the Middle Ages, yellow fever that decimated Napoleon's forces in Haiti during the early nineteenth century, and influenza that claimed the lives of as many as 50 million people in 1918 (Zietz and Dunkelberg, 2004; Patterson, 1992; Johnson and Mueller, 2002). In the twentieth century, public health knowledge and interventions increased, particularly in more developed countries, reducing the burden of infectious diseases (Armstrong et al., 1999). Industrialization and urbanization influenced improvements in sanitation, structural development (e.g., window screening), and vector control that collectively lowered transmission rates by reducing the population's contact with infectious agents (Armstrong et al., 1999). In addition, the discovery of penicillin in 1928 and the continual development of vaccines ushered in an age of treatment and prevention strategies that many believed could eradicate infectious diseases from the globe (Clardy et al., 2009; 1999).

This idea was personified by organizations that made pronouncements to 'take up arms' against the most burdensome diseases. A well-known example comes from the Rockefeller Foundation, an organization that allocated substantial resources in the early twentieth century to combat yellow fever in the United States and other highly impacted territories, efforts that established precedence for future work (Fosdick, 1989). After World War II, new health organizations were established, including the US Centers for Disease Control and the World Health Organization (WHO) that led multiple campaigns to completely eradicate specific infectious diseases. One of the most notable efforts was the vaccination campaign against smallpox, a highly infectious viral disease that was completely eradicated by 1980 (Henderson, 2009). These campaigns established a great confidence and optimism in the ability to combat and control infectious diseases worldwide.

Despite these achievements, infectious diseases still pose a considerable threat today (Jones et al., 2008). Currently, it is estimated that at least 25% of total global mortality is attributable to infectious diseases, translating into over 15 million deaths per year (Mathers et al., 2008). The majority of deaths occur among children less than 5 years of age, living in countries with low to middle incomes (Mathers et al., 2008). Certain diseases have greater mortality, such as acute respiratory infections, tuberculosis, diarrheal diseases, malaria, measles, and HIV/AIDS, which account for 9 out of every 10 infectious disease deaths (2001).

Data from the past 30 years reflect various degrees of resurgence or reemergence of different infectious diseases worldwide. Two important examples of this phenomenon include the increased incidence of wild-type poliomyelitis across geographic pockets of Northern Africa, as well as an increase in the number of individuals being infected by the mosquito-borne disease caused by dengue viruses. Additionally, novel infectious diseases continue to emerge in virtually every region of the world. Examples include Hendra virus, discovered in 1994 in Australia (Murray et al., 1995); Nipah virus, identified in 1999 as the causative agent of outbreaks among pig farmers in Malaysia (Chua et al., 2000); severe acute respiratory syndrome (SARS) responsible for an outbreak of respiratory disease in multiple countries in 2003 (Marra et al., 2003; Peiris et al., 2003); and the 2009 emergence of a new influenza strain, originating in North America, responsible for the first pandemic of the twenty-first century (2009b). In public health, these types of events are referred to as emerging or reemerging infectious diseases, or collectively known as emerging infectious diseases (EIDs). EIDs have been defined as infections that are newly recognized in a population or have existed previously but are rapidly increasing in incidence or geographic range (Morse, 2004; Morens et al., 2004; Fauci, 2005, 2001; Institute of Medicine (US). Committee on Emerging Microbial Threats to Health et al., 1992). EIDs can be considered emerging, recently reemerging/resurging, or deliberately emerging, depending upon the pathway of emergence (Morse, 2004; Fauci, 2005; Morens et al., 2008).

EIDs are influenced by a wide variety of often complex factors, including ecology, human behavior, globalization, microbial adaptation, and public health infrastructure (Morse, 1995, 2004; Lashley, 2003; Morens et al., 2004, 2008; Fauci, 2005; Jones et al.,

This article is a reprint of B.D. Anderson, G.C. Gray, Emerging and Reemerging Infectious Diseases, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

2008). More recently, the threat of bioterrorism, or the deliberate release of viruses, bacteria, or other agents used to cause illness or death in people, animals, or plants (Inglesby et al., 2002; Jernigan et al., 2002; Traeger et al., 2002), has added its own complexities to how EIDs affect global health. A number of recent bioterrorism events have had a dramatic impact on public health policies and resource allocations. New research and technology have provided better detection and response capabilities, as well as basic general knowledge of the various factors and determinants affecting the emergence and spread of EIDs; however, much is still unknown. This article offers a review of the most relevant literature associated with EIDs, as well as perspectives on how to address the most critical future public health questions.

Global Distribution

EIDs exist in most regions of the world, often with distinct and identifiable transmission patterns that are driven by various predictors or risk factors. These include the globalization of travel and trade, country and individual social-economic status, as well as population dynamics. Risk factors are used to identify trends in the movement of EIDs throughout various populations. When coupled with Geographic Information Systems mapping software, transmission patterns can be modeled, offering a pictorial view of EID distribution. These models are very useful, allowing for predictions to be made as to where future EID events are likely to occur and estimating the impact of public health interventions.

Globalization

Modern globalization has created ubiquity in world travel and trade. For example, a piece of fruit that is grown in Chile today can be purchased in a market on the other side of the world in 1–2 days. EIDs travel via these rapid global transport systems as made evident by the frequent international foodborne epidemics and zoonotic disease outbreaks that have occurred over the past few decades. SARS in 2003 demonstrated how quickly a highly transmissible respiratory pathogen can be spread, originating in China, and making its way to more than 15 countries in just a few months (Shen et al., 2004). Another example is the cholera outbreak that began in Haiti following a devastating earthquake in 2010, with genomic evidence suggesting that the epidemic *Vibrio* strain that ignited the outbreak was likely carried into the country by foreign security forces (Keim et al., 2011; Chin et al., 2011; Pun, 2011; Piarroux et al., 2011; Ali et al., 2011). These types of events make control extremely difficult, reflecting how quickly EIDs can be transmitted and established in new populations before public health officials can intervene.

EIDs and Economic Status

Geographically, EIDs are often more highly prevalent among underdeveloped and economically disadvantaged populations. Along with a high incidence of EIDs these populations also experience a greater severity from infections, often translated into higher rates of mortality (Farmer, 1996). This trend is attributed to various social determinants of health that elevate the susceptibility of an individual or population to infection (Marmot, 2005). Poverty both promotes and results from social determinants including access to health care, clean water, food, and other important environmental factors that influence disease transmission (Marmot, 2005). The cyclic nature of this relationship makes public health interventions complicated, since most, if not all, determinants must be addressed in order to have a lasting positive impact.

The socioeconomic status of a country can be an important determinant for the transmission of EIDs, influenced by both the availability of an appropriate public health infrastructure and the necessary resources to carry out prevention and control strategies. This could include instituting effective surveillance systems, as well as providing adequate health-care services to individuals affected by EIDs. Without this necessary capacity, a disease can quickly become well established or endemic in a population before a public health response can be initiated, if one is initiated at all.

Historically, tuberculosis, chiefly caused by *Mycobacterium tuberculosis*, is an EID associated with economics, often being coined a 'disease of poverty' due to the increased impact it has on economically poor individuals. Today, data indicate 95% of all tuberculosis cases and deaths occur in the developing world (2012b). In the past 30 years, tuberculosis has begun to reemerge across the globe, partly due to the emergence and spread of HIV, which is now a primary risk factor for tuberculosis transmission. Nearly half of all individuals in the developing world who have HIV also are coinfecting with *M. tuberculosis* (2012b). This emphasizes the importance economics play as a driver for disease emergence and reemergence, as well as the treatment strategies available for those infected.

Despite a disproportional distribution of EIDs in low- and middle-income countries, high-income countries experience their own burden of EIDs. In the United States, West Nile virus continues to cause disease in man. Lyme disease is also well established with an annual incidence that has increased in over the past 10 years, reaching over 30 000 and 60 000 reported annual cases in the United States and Europe, respectively (Radolf et al., 2012). In 2003, the global pet trade contributed to an outbreak of monkeypox virus in the United States that originally infected individuals who had close contact with prairie dogs purchased as pets through a common supplier. Epidemiological studies traced the origin of this outbreak back to an exotic African rodent species that transmitted the virus to the prairie dogs during transport to the United States (Reed et al., 2004).

Higher socioeconomic countries also experience a substantial burden of foodborne related EIDs, the more common pathogens being bacteria, including *Salmonella* spp., *L. monocytogenes*, *Brucella* spp., *Campylobacter* spp., and pathogenic strains of *E. coli* (Newell et al., 2010). Even with strict regulations on food production, outbreaks frequently occur due to the centralization and mass production by the food industry, which is capable of distributing large quantities of food over vast geographic areas. In this

type of system, if food becomes contaminated, then rapid dissemination of the pathogen before detection is much more likely. This is especially dangerous when the pathogen being disseminated is very pathogenic and the population is more susceptible. This was the case when a rare subtype of enterohemorrhagic *E. coli* (O104:H21) was responsible for a foodborne outbreak throughout Europe in 2011 that caused over 3800 cases and 54 deaths (Frank et al., 2011). Upon investigation, the source of the outbreak was found to be sprouts that were grown with contaminated seed attained from a supplier in another country (Buchholz et al., 2011).

Population Density and Expansion

Since 1960, the global population has more than doubled, from 3 billion to nearly 7 billion people (2012a). As the population has grown, population density has also increased, creating in some countries what are called megacities (e.g., Tokyo, Mexico City, New York City, etc.). These cities may have upward of 20 million people or more, sometimes residing in extremely confined geographic areas. These conditions promote the proliferation of new diseases, especially when the pathogen is highly transmissible, forming emerging disease 'hot spots' (Jones et al., 2008; Heymann and Rodier, 2001). In addition, some of these countries operate wet markets where livestock, including poultry and swine, are slaughtered in poor hygienic conditions and sold directly to the public (Webster, 2004). These practices further promote favorable environments for disease emergence, with SARS and highly pathogenic avian influenza (HPAI) virus being recent examples.

In response to rising population densities, many cities have seen an increase in urbanization, particularly away from a city center. This practice is often referred to developmentally as urban sprawl. While the practice has helped to reduce the rate of growing population density inside cities, it has concurrently moved more groups of people into previously undeveloped areas. This rapid expansion in land use and development has combined what was once fairly separated animal and human habitats, allowing for more frequent exposure of humans to potential disease reservoirs, increasing the risk of EID proliferation.

Pathways of Emergence

It has been proposed that EID events occur in two steps (Morse, 2004). A pathogen must first be introduced into a new population and then disseminated within that population. With this construct in mind, understanding the origin of novel microbes becomes critical. Microbes often exist in the environment in a nonpathogenic state, with limited contact with a viable host. However, when appropriate conditions are met, opportunistic microbes can exploit new niches, including human hosts, resulting in a successful introduction. Once successful, this type of event is sometimes referred to as a microbial 'jump' or 'crossover'. This crossing of the species barrier is often necessary before widespread dissemination can occur.

Dissemination is then dependent upon the transmissibility of the pathogen in the new population. Dissemination can occur directly from one host to another, or can establish an intermediate host in its transmission cycle, such as a vector. If a pathogen is unable to be transmitted beyond an immediate or intermediate host, then further dissemination is not possible. These interactions can often be complex, involving pathogen, environment, and host, making it challenging to understand and identify what contributes to the most optimal conditions promoting disease emergence.

Zoonoses

The transmission of a pathogen between animals and humans is known as zoonotic transmission or zoonosis. Zoonosis is perhaps one of the most important pathways of emergence, with an estimated 75% of all known EIDs originating from some type of animal reservoir (Taylor et al., 2001). Disease examples include HIV/AIDS, Lyme disease, plague, SARS, several hemorrhagic fevers, and zoonotic influenza. Each of these possesses a unique etiology, and though it is not an exhaustive list, it highlights the diversity of disease emergence related to zoonosis. Additionally, effectively controlling zoonotic diseases is particularly difficult, since recognizing an emerging zoonotic disease often does not occur until a major outbreak is already underway. If the responsible zoonotic pathogen is highly transmissible, then future epidemic spread occurs even after recognition.

As previously discussed, population growth has had a drastic impact on society. Greater zoonotic disease potential can result from this growth primarily due to an increased interaction between humans and animal habitats, Figure 1. Population growth has also resulted in a higher demand for food commodities. To meet this growing demand, industrialization of food production is increasing, especially in developing countries. This is true of all types of food, including meat production that has moved away from small farms toward large-scale cattle, poultry, and swine operations, Figure 2. These sites have been able to streamline meat production; however, it comes at the cost of creating favorable environmental conditions for the zoonotic transmission of opportunistic microbes (Drew, 2011).

Other food acquisition practices pose a greater risk of acquiring an EID. This includes the long-standing practice in Africa, Asia, and the Americas of hunting and consuming wild animals, also called bushmeat. Eating bushmeat has been associated with a number of new diseases, including two highly fatal hemorrhagic diseases caused by Ebola and Marburg viruses (Peters, 2005; Wolfe et al., 2005). Additionally, the practice of consuming raw or unpasteurized milk products (e.g., milk, cheese) can increase the transmission risk of certain zoonotic bacteria, such as *L. monocytogenes*, *Brucella* spp., and *Campylobacter* spp. This is particularly common in areas where pasteurization is not an accepted practice.

Figure 1 The risk of zoonotic transmission of a pathogen is increased with man's close and frequent contact with other species.

Figure 2 Large dense populations of animals, particularly in herds, can promote zoonotic pathogen transmission to man.

Vectors

Some EIDs are vector-borne, caused by the transmission of a pathogen through the feeding activity of a vector, usually an arthropod. Some of the most common and effective vectors are insects including flies and flees, as well as arachnids such as ticks and mites. These vectors are often attracted to humans and animals because they are obligate blood feeders, using biting or piercing mouthparts to obtain a blood meal from their host. Pathogens have coevolved with vectors to exploit this behavior, often relying on transmission to allow for the propagation of new progeny. An example of a model vector that does this is the mosquito, which is the most widely distributed and abundant vector in the world. Mosquitoes are of particular concern due to their sometimes aggressive feeding behavior and ability to effectively transmit a broad range of pathogens, causing diseases such as malaria, dengue fever, and many others.

In terms of importance to emergence, it has been suggested that vector-borne EIDs constitute nearly a quarter of all EID events occurring in the last decade (Jones et al., 2008). Also, there has been an increase in the total number of vector-borne EIDs during this same time period, while other types of EIDs have slightly decreased (Jones et al., 2008). Increased human population density and changing demographics seem to be associated with this rising trend of vector-borne EIDs, as well as climate change that some have suggested is promoting an expansion in vector distribution and range (Jones et al., 2008; Epstein, 2001).

Animals are also important in the life cycles of vector-borne diseases, since many can be competent hosts and serve as reservoirs for different pathogens. In fact, some EIDs only occur when humans become an incidental or dead-end host in an already established transmission cycle between an animal and vector. This is true for Japanese Encephalitis (JE), a flavivirus transmitted by certain mosquitoes, causing viral encephalitis cases primarily in Asia. For JE, humans are dead-end hosts, capable of infection if bitten by an infected mosquito, but unable to amplify and transmit the virus further, whereas, swine and other wild birds are able to propagate the virus and maintain a complete transmission cycle. Hence, if humans are removed from the environment, the virus would still be sustained as long as the vector, pathogen, and reservoir were to remain.

Factors Associated with EIDs

Since the early 1990s, discussion has been centered on the factors that are most associated or attributable to EIDs. A report published by the Institute of Medicine in 1992 originally identified six contributing factors (Institute of Medicine (U.S.). Committee on Emerging Microbial Threats to Health et al., 1992). Since the list was published, new emerging threats have resulted in additional factors being added, all thought to be important contributors by the global health community, Table 1.

This list provides guidance as to where research efforts and interventions should be targeted. It is important to note that many of these factors are often interrelated with each other. For instance, a lack of political measures will often result in the breakdown of public health measures. Economic development and land use can be associated with technology and industry, as well as changing ecosystems, and shaping conditions of poverty. Hence, effective interventions must be multidimensional for sustained change.

Ecological Changes

Perhaps one of the most apparent and pervasive factors affecting the incidence of EIDs is environmental alterations that result in a drastic change in ecology. One common ecological model works from a premise that disease occurs at the intersection of environment, pathogen, and host, Figure 3. A change to any one of these entities could impact the disease outcome. It has been suggested that classical ecological tools are limited in their ability to effectively assess the multifaceted complexities of EIDs. This is clearly indicated by the limited number of published studies that have effectively evaluated EIDs from an ecological perspective (Meentemeyer et al., 2012). An ecological relationship could be as simple as the symbiosis of certain types of fungus and plants where no other factors play a role in the survival of everyone. Others can be much more complicated, such as the multistage life cycle of the guinea worm (cause of the disease dracunculiasis), a parasitic nematode that uses two different species, a copepod and humans, to complete its life cycle. These parasites are impacted by human movement, water availability, copepod abundance, as well as climate, all of which can impact the nematode life cycle.

However, the research that does exist suggests that the most important ecological changes encouraging EIDs are those that put humans in closer or more frequent contact with current or potential pathogen reservoirs. For instance, the incidence of Lyme disease in the United States and Europe seems to be associated with the number of available hosts in a given area. Deer and small mammals play an important role in the life cycle of ticks that vector the spirochete causing Lyme disease. Studies have shown that host populations directly correspond to tick abundance, often influenced by ecological factors that promote population growth (Levi et al., 2012). When this is coupled with urbanization and reforestation, transmission can drastically increase, since both the host and environment serve as the drivers for disease emergence.

Climate Change

Evidence shows that the earth's average surface temperatures have increased at least 0.6°C over the past century (Houghton and Intergovernmental Panel on Climate Change. Working Group I., 2001). While many agree with the empirical evidence of rising temperatures, there is still controversy as to why the earth is warming. Some argue that the earth is experiencing a natural temperature fluctuation similar to what has occurred throughout history, citing previous ice ages and warming periods. Others have suggested that the rising temperatures are attributed to increased atmospheric concentrations of carbon dioxide related to the

burning of fossil fuels and deforestation. Despite the discourse, the reality of climate change in the context of EIDs remains an important topic, with research showing associations between disease indicators and climate factors (Patz et al., 1996; Epstein, 2001).

Climate change primarily impacts the range of infectious diseases, particularly those that are transmitted by vectors. Warmer temperatures allow vectors to more readily survive conditions at higher altitudes and latitudes, as well as having shorter periods of overwintering. Weather patterns are also influenced, as the hydrolytic cycle can be disrupted by warmer ocean temperatures, causing severe weather at greater frequency. Particularly concerning are weather events that release high volumes of rain, as they may result in temporary explosions in vector populations, especially mosquitoes.

Microbial Adaptation and Change

From a pathogen perspective, microbial adaptation and change significantly contribute to the likelihood that a microbe will become pathogenic in a population. As mentioned, when certain environmental conditions are met, a microbe can experience alterations in genetic makeup that can affect its pathogenicity or virulence. This type of adaptation can either occur gradually or rapidly by means of random mutations, reassortments, or adaptive pressures brought on by stressors such as antimicrobial agents.

A good example of microbial adaptation is demonstrated by the influenza A virus, an RNA virus that has been shown to undergo both gradual and rapid genetic changes. Just in the last 20 years, new variants of influenza have caused major human outbreaks, including HPAI subtype H5N1, first detected in 1997 (1997) and the pandemic influenza subtype H1N1, first detected in 2009 (2009a). Influenza A contains two surface proteins (glycoproteins), called hemagglutinin (HA) and neuraminidase (NA): HA proteins are associated with viral attachment and cell entry using a fusion pathway, while NA proteins regulate the release of progeny virus from an infected cell. Antigenic drift and shift are two mechanisms that create variations in the antigenic properties of these two proteins that allow influenza A to bypass the acquired immunity of a population, Figure 4. Antigenic drift occurs when small point mutations accumulate gradually, altering the antigenic properties of the two surface proteins. This can cause population immunity to partially decrease, resulting in seasonal epidemics. Antigenic shift involves major changes in proteins, sometimes through the swapping of entire gene segments. The genetic reassortment occurs when two or more unique viruses infect the same cell and generate mixed progeny viruses (Chen and Deng, 2009; Kaye and Pringle, 2005). In particular, genetic reassortments of the HA antigens may result in large worldwide epidemics or pandemics. Waterfowl are thought to be the largest source of diverse viruses from which gene reassortment may occur, as they are known to carry viruses with 16 different HA proteins. When a population has no or little immunity to a new subtype and the new subtype is highly transmissible, pandemics may result.

Like influenza A virus, other pathogens undergo similar mechanistic adaptive changes and sometimes variation results from external pressures that promote microbial evolution. Antibiotic resistance is an example of this kind of adaptation. Since their discovery, the use and variety of antibiotics have greatly increased over time and many pathogens have adapted to their presence. These antimicrobial resistant pathogens are having an increased impact upon clinical care and medical costs.

Bacteria, such as methicillin-resistant *Staphylococcus aureus* and multidrug resistant *M. tuberculosis*, are good examples of the severe impact that this type of microbial adaptation can have on individual health outcomes. Individuals infected with these bacteria are often prescribed newer and more expensive, 'last defense' antibiotics. These diseases may be life-threatening and require specialized care. Hospitalized patients with these resistant pathogens may seed the hospital staff and environment and cause nosocomial transmission among immunocompromised patients.

Important EID Examples

EIDs result from a large variety of causative agents, each one possessing a unique etiology and ecology. Agents may be organized according to transmission pathways, genetic markers, or the pathology a pathogen might exhibit in a population. Most often,

Figure 4 Graphical representation of antigenic drift and shift among influenza A viruses. Top panel: Antigenic drift – minor genetic changes (e.g., through mutation) lead to slight changes in surface glycoproteins or season variation in strains. Bottom panel: Antigenic shift – exchanges of entire segments of genome lead to major changes in the surface glycoproteins, which may lead to pandemics.

however, EIDs are categorized into bacteria, virus, fungus, parasites, and more recently prions. [Table 2](#) presents key examples of each of these disease categories.

Conclusions

As the world's population rises and public health problems increase in complexity, it will be critical to establish innovative and dynamic strategies to counter EID threats. These strategies should include the reinforcement of public health systems, better diagnostics for EIDs, stronger surveillance systems, and better interdisciplinary and international collaborations. A novel interdisciplinary strategy, called One Health, is gaining popularity as an approach that attempts to focus efforts on complex public health issues such as EIDs.

Public Health Infrastructure

Public health infrastructure is critical to the current mitigation and future prevention of EID events. An effective infrastructure should include the following: a legal framework that allows for enforcement of public health measures and a system to monitor outcomes; dissemination and utilization of health knowledge, including the training of health workers; and physical environments or services conducive to targeting important health threats, like sanitation infrastructure (e.g., sewers). Infrastructure can subsist on a local level, but most often relies upon the coordination and leadership of national-level governments, providing guidance for task prioritization and implementation. However, national and international organizations can also provide assistance by supporting government-led efforts with technical and financial resources, or filling in the necessary gaps of a fragmented infrastructure.

EID Diagnostics

Diagnostics are an important tool for identifying and characterizing infectious disease agents from both clinical and environmental samples. Common techniques include molecular assays, such as multiplexing, microarrays, deep sequencing, and traditional and real-time polymerase chain reaction, as well as immunoassays, including variations of the enzymelinked immunosorbent assay and other techniques exploiting antigen and antibody binding activity. The variety and availability of these techniques have greatly improved over the last two decades, with significant increases in sensitivity and specificity, as well as marked decreases in costs. For instance, the cost of full genome sequencing of a moderately large virus has seen substantial reductions in the past decade, dropping from tens of thousands of dollars per run to a couple thousand dollars, with much more accurate analysis. Much of this improvement can be attributed to new technological developments, such as third and fourth generation sequencing that is greatly improving novel pathogen detection capabilities.

Table 2 Examples of recent human emerging infectious disease threats

Emerging infectious disease threat	Pathogen	Emerging/reemerging	Primary transmission	Key geographic area(s)
Bacteria				
Bartonella infections	<i>Bartonella</i> spp.	Emerging	Zoonotic	Australia, Europe, United States
Vancomycin-resistant <i>Staphylococcus aureus</i> infections	<i>Staphylococcus aureus</i>	Reemerging	Person-to-person	Worldwide
Pathogenic <i>Escherichia coli</i> infections	<i>Escherichia coli</i>	Emerging	Foodborne	Europe, United States
Cholera	<i>Vibrio cholerae</i>	Reemerging	Waterborne	Africa, Asia, South America, Haiti
Plague	<i>Yersinia pestis</i>	Reemerging	Vector-borne	Africa, Asia, South America, United States
Typhoid fever	<i>Salmonella typhi</i>	Reemerging	Foodborne, waterborne	Africa, Asia, Latin America, Caribbean
Diphtheria	<i>Corynebacterium diphtheriae</i>	Reemerging	Respiratory (person-to-person)	Eastern Europe, India
Multidrug-resistant tuberculosis infections	<i>Mycobacterium tuberculosis</i>	Reemerging	Respiratory (person-to-person)	Worldwide
Lyme disease	<i>Borrelia</i> spp.	Emerging	Vector-borne	Eastern Asia, Europe, United States
Fungal				
<i>Cryptococcus gattii</i> infections	<i>Cryptococcus gattii</i>	Emerging	Environmental exposure	Australia, Canada
Parasite				
Cyclosporiasis infections	<i>Cyclospora cayetanensis</i>	Emerging	Foodborne, waterborne	Worldwide
Drug-resistant malaria	<i>Plasmodium</i> spp.	Reemerging	Vector-borne	Africa, Asia, South America
Protein				
Variant Creutzfeldt–Jakob disease	Prion	Emerging	Zoonotic, foodborne	Europe
Virus				
West Nile fever	West Nile virus	Reemerging	Vector-borne	Africa, Asia, Europe, North America
Hantavirus pulmonary syndrome	Hantavirus	Emerging	Zoonotic	Canada, East Asia, Europe, South America, United States
Dengue fever	Dengue virus	Reemerging	Vector-borne	Central Africa, Central America, Latin America, Southern Asia
Yellow fever	Yellow fever virus	Reemerging	Vector-borne	Central Africa, South America
Lassa fever	Lassa fever virus	Emerging	Zoonotic	Central and Western Africa
Marburg hemorrhagic fever	Marburg virus	Reemerging	Zoonotic	Central Africa
Ebola hemorrhagic fever	Ebola virus	Reemerging	Zoonotic	Central Africa
Rift Valley fever	Rift Valley fever virus	Reemerging	Vector-borne	Africa
Hendra virus infection	Hendra virus	Emerging	Zoonotic	North-eastern Australia
Nipah virus infection	Nipah virus	Emerging	Zoonotic	Asia
Highly pathogenic avian influenza	H5N1 influenza virus	Emerging	Zoonotic	Asia
Severe acute respiratory syndrome	SARS coronavirus	Emerging	Respiratory (person-to-person)	Asia ^a
2009 pandemic influenza	2009 H1N1 influenza virus	Emerging	Respiratory (person-to-person)	Worldwide
Japanese encephalitis	Japanese encephalitis virus	Reemerging	Vector-borne	Asia

^aOriginated in Asia, but had rapid global transmission.

A major need is the better recognition of EIDs, especially in low-resource areas where EIDs are common. This can be accomplished by prioritizing laboratory infrastructure development, continuing to direct efforts in targeting disease 'hot spots' where EID outbreaks are most likely to occur. Emphasis should be placed on making new diagnostic assays timely, affordable, and feasible for laboratories with limited resources. In addition, employing assays that are able to detect multiple agents in a single specimen is important in EID management. This kind of technique allows for more rapid identification of causative agents, an important component in how public health responses are planned and delivered.

Global Surveillance and Communication

Disease surveillance is defined as the ongoing systematic collection, consolidation, and analysis of outcome specific data for the purpose of planning, implementation, and evaluation of various health-related events (Thacker, 1988). Many information and surveillance networks that are currently in place can be characterized as fragmented or unrepresentative of actual disease circulation in a population, making it difficult to estimate actual incidences. There have been some successes in improving surveillance capabilities, particularly passive surveillance that uses techniques such as monitoring healthcare clinics and emergency rooms for various health outcomes indicative of an EID.

For instance, global influenza surveillance, following the 2009 H1N1 pandemic, received substantially more prioritization and resource allocations from countries that were lacking such capabilities beforehand. This has resulted in a rather comprehensive collection and dissemination of data to stakeholders worldwide, through a network called FluNet. This network is overseen and coordinated by WHO, and helps provide a more comprehensive resource regarding the incidence and circulation of different strains of influenza. Information is used not only to enhance outbreak response, but is also the source of prototype strains that are used in annual seasonal vaccination manufacturing. This is an example of how successful surveillance can greatly improve the public health response capabilities.

For EIDs this may be more difficult, only since it takes a large amount of coordination and resources to create global surveillance for any specific pathogen. Furthermore, loweconomic countries often do not have the necessary resources to carry out such endeavors. The Internet may be useful in supporting countries that lack traditional surveillance capabilities, as has been demonstrated by the international e-service called ProMED-mail. This service is a consortium of public health professionals that disseminate disease outbreak updates, often in real time, through a global e-mail distribution list. Since telecommunications are becoming well established, even in low-economic countries, this has proven to be a very practical approach, providing the international community with reliable information and even sometimes serving as a first report of an index case. Further developing these types of approaches will be useful in communicating EIDs, pre- and postevent.

International Collaboration

Today, EIDs impact our entire world. It will be important that governments and agencies concur with the need for strong international communication and collaboration regarding EID events. This will include the sharing of resources and knowledge, particularly regarding EIDs that are considered a global threat. It is also ideal that low-economic countries receive priority in the enhancement of their public health systems, since a large proportion of EID risk exists in these areas. Collaborations offer unique diversity in expertise, improve cultural competencies, and enhance response efforts in the event of an EID outbreak.

'One Health'

It is clear that EID ecology is often complex, requiring a sophisticated, interdisciplinary response to mitigate disease impact. One attempt to address these complexities has been coined 'One Health'. One Health is a moniker for the interdisciplinary approach, bringing together human, animal, and environmental health professionals, to address complex global health problems. While the terminology may be relatively new, the foundations of the approach are not. Throughout history, individuals from different disciplines have often worked together to create solutions for some of the most important health threats. One Health attempts to convert those cooperative successes into a practical methodology to be used in future public health problems.

One of the strongest arguments for One Health is the role zoonoses play in the emergence of new infectious diseases, and the recognized long-standing gap of cooperation that has existed between the fields of animal and human health. As previously described, the global impact of HIV, H5N1 avian influenza, SARS, and 2009 H1N1 pandemic influenza, all diseases with origins from animal reservoirs, have led to a consortium of doctors, veterinarians, and public health officials beginning to work together to identify effective solutions that bridge the gap between each discipline. In addition, experts from fields of geography have begun to pursue new models to help predict the movement of different EIDs. Engineers are developing new technologies, based upon the recommendations of field workers that may mitigate contamination of food and water supplies. Economists are calculating the cost effectiveness of vaccination campaigns to help guide policy makers in better using resources.

Overall, One Health is an approach that can improve effectiveness of public health response and interventions, as it allows for a more targeted application of multiple areas of expertise, not relying on a single discipline approach that may not address all of the minute facets that accompany most public health problems of today. To be successful, it will require an intentional effort of current public health professionals reaching out to one another, to strengthen collaborations, communication, and the ability to be open to novel ideas. Since this approach promotes flexibility, it should be able to adapt to the rapid changes demonstrated by emerging

diseases in the last two decades. It is this characteristic that makes One Health not just a temporary solution, but a philosophy that can have serious long-term impact on EID morbidity and mortality.

Acknowledgments

We thank Whitney S. Krueger, PhD, for her much appreciated editorial review of this work.

Glossary

Ascospore The meiospore of Ascomycota produced inside an ascus.

Ascus (pl. asci) A sac-like structure characteristic of Ascomycota. An ascus usually contains eight ascospores.

Axenic (of cultures) A pure culture of microorganism that is completely free of the presence of other organisms, uncontaminated, consisting of a single organism.

Conidium (pl. conidia) A specialized, nonmotile, asexual spore of mitosporic fungi.

Defensive mutualism A form of symbiosis where the host is defended from predation or disease by other symbiont.

Endophyte A microbe growing within tissues of a plant.

Endophytic Living within tissues of a living organism.

Epibiotic Living on the surface of a living organism.

Epiphyllous A microbe growing on the surface of a leaf.

Epiphyte A microbe or plant that lives on the surface of a plant.

Hypha (pl. hyphae) One of the filaments of a mycelium. A basic, threadlike element that forms the thallus of most fungi.

L-form A wall-less protoplast form of a bacterium.

Loco An unusual behavior and neurological syndrome of grazing animals poisoned by certain legumes.

Mutualistic symbiosis A form of symbiosis where both organisms benefit from the association, with an overall increase of fitness and survival.

Mycelium (pl. mycelia) A mass of hyphae; the thallus of a fungus.

Mycosome A wall-less protoplast form of a fungus.

Mycotoxin A compound produced by a fungus that is toxic to humans and other organisms.

Rhizophagy cycle A nutritional process where symbiotic microbes cycle between a root intracellular phase and a free-living soil phase. Microbes (bacteria or fungi) acquire soil nutrients in the free-living soil phase; nutrients are extracted from wall-less protoplast forms of microbes oxidatively in the intracellular endophytic phase.

Stroma (pl. stromata) A mass or matrix of mycelium, with or without tissue of the host or substrate, in or on which spores or fruit bodies bearing spores are produced.

Volatile organic compounds (VOCs) Are organic chemical compounds that have high enough vapor pressures under normal conditions to significantly vaporize and enter the atmosphere.

Defining Statement

Endophytic associations between microbial and autotrophic organisms in nature are ubiquitous. Because of the complexity of the endophytic associations with their hosts we are only starting to understand these interactions. In this article, we compare the biology and ecology of different groups of endophytes associated with hosts. The functional roles of endophytic microbes are also discussed. We also evaluate the potential of endophytic microorganisms as sources of bioactive metabolites with potential use in agriculture and medicine.

Introduction

Microorganisms are found virtually in every biotic and abiotic niche on earth. This includes extremophiles living in deserts, rocks, thermal springs, freshwater, marine, and arctic environments, and associated with terrestrial and aquatic animals. A wide diversity of microorganisms may be isolated from most terrestrial and marine plants. Microorganisms are present on the surface of and within tissues of most parts of plants, especially the leaves. When microbial organisms colonize a plant and the plant tissue is healthy, the relationship between the microorganism and its host plant may range from latent pathogenesis to mutualistic symbiosis. Therefore, the microbial organisms may be latent pathogens, epiphytes (epibionts), or endophytes (endobionts).

[☆]*Change History:* November 2018. Mariusz Tadych and James F. White updated the text and references. This is an update of Tadych, M., White, J.F., 2017. Endophytic microbes. In: Reference Module in Life Sciences. Elsevier.

This article is an update of M. Tadych, J.F. White, Endophytic Microbes, *Encyclopedia of Microbiology (3rd Edn)*, edited by Moselio Schaechter, Academic Press, 2009, pp. 431-442.

Endophytes are generally any organisms that under normal circumstances are contained within tissues of living plants (usually autotrophs) without causing noticeable symptoms of disease, and the host tissues remain intact and functional. However, the same organisms may also be described as saprobic or pathogenic at another time; for example, when the host is stressed, some endophytes may become pathogenic. The delicate balance between host and endophytic organisms seems to be controlled in part by chemical factors, for example, herbicidal natural products produced by the fungus versus antifungal metabolites biosynthesized by the host plant.

The term 'endophyte' is derived from the Greek *endon* (within) and *phyte* (plant), and was introduced by Heinrich Anton de Bary in 1866 and applied to any organism found within a plant. Traditionally, the term had been broadly applied to fungi in plant tissue, including the mycorrhizal fungi in plant roots. However, some authors do not include mycorrhizal fungi in this group. The term endophyte has also been adapted to other microorganisms, such as endophytic bacteria. The associations of endophytic organisms with their host plants are varied and complex and we are only starting to understand these interactions. Endophytic microbial organisms often contribute to the normal health and development of their hosts in exchange for a relatively privileged niche. Microbial endophytes have been isolated from tissues of algae, mosses and hepatics, ferns and fern allies, grasses, other herbaceous plants, and trees growing in tropical, temperate, boreal, and arctic environments.

Endophytes represent a large reservoir of undiscovered genetic diversity. Species composition of endophyte assemblages and infection frequencies vary according to (1) host species, (2) growth stage of the host, (3) tissue type, (4) the age of host organs and/or tissues, (5) position in the canopy and associated vegetation, and (6) site characteristics, such as elevation, exposure, and latitude. Usually, one to a few species dominate the endophyte community, while the majority of the species are rare. Distribution of rare and incidental species is influenced more by site than by host, and the number of rare and incidental species isolated is proportional to the intensity of sampling.

Many plant fungal endophytes are transmitted horizontally by production of conidia or other spores on plants that may spread to adjacent uninfected plants, and are not directly inherited through germplasm from the previous generation of the host. Therefore, with each host generation, environmental fungi must compete to colonize the empty niches within new host individuals. Alternatively, some endophytes, including *Epichloë* species, grow intercellularly throughout aboveground parts of plants and are transmitted vertically via seeds. These endophytic fungi are spread by hyphae growing into the developing seeds or vegetative parts of infected maternal host plants.

Epibiosis is another type of association of two organisms, the epibiont and the basibiont. The majority of organisms that exist on the surfaces of plants are referred to as epibionts or epiphytes. The epibiotic organism may be sustained entirely by nutrients and water received nonparasitically from within the host (basibiont) on which it resides. However, the interaction of epibiont with basibiont is usually unknown. In some epibionts water and nutrients are taken up entirely from suspended soils and other aerial sources such as dead host tissues, airborne dust, mist, and rain. Any negative effect on the host, if it occurs, is indirect. In general usage the terms epiphyte and epibiont are used interchangeably.

The assemblage of epiphyllic flora on the surface of healthy plant leaves is usually composed of bacteria, yeasts, and filamentous fungi that belong to different systematic categories. The density and the number of epiphyllic microorganisms can rapidly change and it strongly depends on environmental conditions, host species, habitat of the host, and the age and the surface structure of the organ on which the epiphyllic organism resides.

While some fungi are adapted to the plant surface, the community also includes propagules of airborne species, fungi that would not otherwise be considered epibionts. The surface of the plant, especially the leaf is an extreme environment. Though plants may leak nutrients through the cuticle, the surface is dry, waxy, and affected by UV radiation. Epibionts have many obvious characteristics that enable continuation through the stressful conditions of the leaf surface. For example, some epibionts can digest lipidic substrates, and thus may utilize the waxy layer covering the leaf. Epibionts are likely to be melanized, and thus able to resist UV radiation. Epibiotic yeasts are able to multiply during the short periods of appropriate environmental conditions. Although epibiotic organisms differ markedly from endophytes, it has been shown that some endophytic fungi are also able to produce epiphytic stages with fungal reproductive structures on the surface of the host plant.

Bacterial Endophytes

For approximately 60 years endophytic bacteria have been observed to exist within plants. Bacterial endophytes similar to endophytic fungi are microorganisms that live inside plant tissues and can be isolated from surface-disinfected plant tissues or extracted from within a plant. Although the bacterial endophytes do not visibly harm the host plant, traditionally they were assumed to be latent pathogens or contaminants.

Endophytic bacteria have been isolated from several tissue types of numerous plant species including both mono- and dicotyledonous plants. It is assumed that the root zone is the primary site where endophytic bacteria enter plant tissues. However, aerial portions of plants may also be used for entry. Inside a plant the endophytic bacteria can spread from point of entry throughout the entire plant. Various studies indicate that endophytic bacteria inhabit mainly intercellular spaces of plant tissues, but they can also live in intracellular spaces and inside the vascular system. Variations in the populations of endophytic bacteria have been reported, and they depend on plant species, plant age, tissue type, and time of sampling and environmental conditions. Generally, bacterial endophyte populations are larger in roots and gradually decrease in the stems and leaves. Active exchange can also occur between epiphytic and endophytic populations. Although leaf surfaces and interior spaces of a plant are two different

environments to which the foliar bacteria have to adopt to survive and multiply, some of the bacteria can colonize both the surfaces of the leaf and the interior of a plant. Because of the dual colonization of interior and exterior spaces of the plants, distinction between epiphytic and endophytic bacteria may be difficult in practice. The endophytic colonization of plants is probably the standard for plant-associated bacteria to develop sustainable epiphytic populations.

Endophytic bacteria in native and agronomic plants that have been reported most commonly are represented by a broad range of taxa, including α Proteobacteria, β Proteobacteria, γ Proteobacteria, Firmicutes, Bacteroides, Actinobacteria. For example, *Pseudomonas syringae* is an opportunistic plant pathogen capable of colonizing aerial plant surfaces and leaf tissue. *Pseudomonas* species are sometimes reported as a plant endophyte, and some species of the genus are known for their beneficial associations with host plants and for their antagonistic activity against plant pathogens.

The diversity of bacterial endophytes has been mainly studied using cultivation-dependent techniques. Due to insufficient knowledge about growth requirements of many microorganisms as well as the presence of viable but nonculturable bacterial cells within plant tissues, our knowledge of actual diversity of bacterial endophytes is limited. Recent reports have confirmed detection of a broad spectrum of endophytic bacteria from plant tissues by using culture-independent molecular biological methods. For example, the 16S ribosomal RNA gene is a phylogenetic marker frequently employed to describe the microbial community in natural environments without a need for cultivation. It has been found that isolation from internal tissue based on cultivation-dependent methods captured less than 50% of the bacterial community retrieved by cultivation-independent techniques.

Intracellular Root Endophytes: Rhizophagy Symbiosis

In the last several years it has been shown that plant roots internalize bacteria and yeasts into roots cells where microbes appear to be degraded in time – in a process denominated as ‘rhizophagy’ to denote that roots appear to be ‘eating’ microbes. It has become clear that certain microbes are not completely degraded, and instead cycle between a naked-protoplast phase inside root cells and a free-living walled-cell phase in soil in a process that has been denominated ‘rhizophagy symbiosis’ or ‘rhizophagy cycle’. Microbes (bacteria and yeasts) acquire soil nutrients in the free-living soil phase; nutrients are extracted from microbes oxidatively in the intracellular endophytic phase. Plants have a limited capacity to sequester micronutrients in soils, while microbes are particularly good at acquiring soil micronutrients using siderophores and hemophores. Because of this it has been proposed that extraction of micronutrients (such as iron) from rhizophagy microbes is the probable function of the rhizophagy symbiosis. In the rhizophagy cycle symbiotic microbes (bacteria or yeasts) grow on the rhizoplane in the exudate zone behind the root meristem. Microbes enter root tip meristem cells before cell walls are fully hardened – locating within the periplasmic spaces between cell wall and plasma membrane. In the periplasmic spaces of root cells, microbes convert to wall-less protoplasts (called ‘L-forms’ in bacteria, and ‘mycosomes’ in fungi). As root cells mature, microbes are exposed to reactive oxygen (superoxide) produced by NADPH oxidases on the root cell plasma membranes. Reactive oxygen degrades some of the intracellular microbes – and likely causes membrane porosity and electrolyte leakage in other microbes, effectively extracting nutrients from them. Surviving microbes in root epidermal cells trigger root hair elongation, and as hairs elongate microbe protoplasts are forced out of root hairs at hair tips, reforming cell walls and cell shapes as they emerge into the rhizosphere where microbes may obtain additional nutrients. Later attraction of microbes to the root exudate zone behind the root tip meristem again places bacteria in position to enter root meristem cells. It is currently thought that most or all plants engage in rhizophagy symbiosis, although very few details are currently known with regard to how the rhizophagy cycle works or how important it is for plant growth and development.

Fungal Endophytes

Many groups of fungi exist as plant endophytes. The fungal endophytes have commonly been divided into two major groups. The first group comprises a large number of fungal species with a broad range of host plants, and the second group includes a smaller number of specialized fungal species that colonize some monocotyledonous hosts. Every plant species examined to date maintains endophytic associations with fungi and this association is a ubiquitous and cryptic phenomenon in nature. Although most of the endophytic fungi belong to the phylum Ascomycota and its anamorphs, Glomeromycota and some Basidiomycota and Zygomycota are also known.

Endophytes associated with healthy organs of nongrass plants are still poorly known. However, fungal surveys conducted during the last 30 years have demonstrated that tissues of the vast majority of nongrass plants are colonized by endophytic microfungi. Plants from over 100 plant families have been reported to host endophytic fungi. Most fungal surveys of angiosperms show that fungi from ascomycetes orders Diaporthales, Dothideales, Helotiales, Hypocreales, Leotiales, Pezizales, Phyllachorales, Pleosporales, Sordariales, Xylariales, and fungal species belonging to basidiomycetous orders Agaricales and Polyporales are frequently encountered as endophytes. Particularly, fungi from the genera *Acremonium*, *Alternaria*, *Chaetomium*, *Cladosporium*, *Cryptocline*, *Cryptosporiopsis*, *Leptostroma*, *Phoma*, *Phomopsis*, *Phyllosticta*, and *Trichoderma* are well represented in endophyte assemblages. Fungal endophytes within the host may inhabit many different tissues of roots, stems, branches, twigs, bark, leaves, petioles, flowers, fruits, and seeds, including xylem of all available plant organs. Endophytic microfungi in tissues of nongrass hosts are usually highly diverse and occur as numerous localized infections that increase in number, density, and species diversity with organ age. It may be because the fungal endophytes associated with nongrass plants generally appear to be transmitted horizontally (i.e., from plant to

plant in populations). The profile of fungal endophyte assemblages in specific organs can be completely different from those in other plant organs or tissues. In general, the main tissues that have been analyzed for the presence of endophytes in woody perennials are the leaves, twigs, branches, and roots; a few studies have looked for endophytes in meristems, flowers, or fruits of woody perennials. However, the profile of fungal endophyte assemblages in flowers and fruits could be radically different than that in other types of plant structures because these organs are young and rapid in development.

The host range, ecology, and geographical distribution of most groups of endophytic fungi are still poorly known. A study by Betsy Arnold (University of Arizona) and François Lutzoni (Duke University) indicated that endophyte infection of host plants increases along latitudinal gradient from the Arctic to the Tropics, with less than 1% to more than 99% of tissue segments (2 mm²) with endophytes, respectively. This study also showed that foliar endophyte assemblages, at both an individual host species and the community level, increases in diversity with decreasing latitude.

Diversity and composition of endophytic fungal communities of almost all plant species examined to date have been assessed mostly by culture-based approaches and have been identified using morphological characteristics with support of molecular analysis for identification of some endophytes that remain sterile in culture. Abundance and diversity of unculturable endophytes is still mostly unknown, limiting our understanding of endophyte infection frequencies, taxonomic composition, and diversity. Many researchers suggest that culture-based methods alone underestimate diversity and misrepresent the taxonomic composition of endophyte communities. Therefore, recently cultivation-independent approaches, such as RFLP analysis and sequencing of rDNA, have gained popularity as a means to assess the diversity and composition of uncovering endophytes with obligate host association, that is, fungal species that do not grow on standard media or fungi that grow slowly and are lost during the culturing process in competitive interactions.

Endophytes of Grasses

Fungal endophytes of grasses are widely studied; with most work concentrating on fungi of the family Clavicipitaceae (Hypocreales; Ascomycota). The following genera of this family have been identified as grass endophytes or epiphytes: *Atkinsonella*, *Balansia*, *Balansiopsis*, *Echinodothis*, *Epichloë*, *Myriogenospora*, and *Parepichloë*. Clavicipitaceous endophytes, also known as e-endophytes, are widespread in grasses; approximately over 10% of all grass species are estimated to harbor clavicipitaceous fungal endophytes. The genus *Epichloë*, with anamorphs previously in *Neotyphodium*, is the most studied group of grass endophytes. These endophytes are found growing systemically in the aboveground tissues of some temperate grass species of the cool-season grasses. Based on the relative costs and benefits to the hosts, these grass–fungal endophyte symbioses have been showed to range from pathogenic to mutualistic. Some endophytic species from the genus *Epichloë* are often considered to be pathogenic and may cause partial or complete sterilization of hosts due to the production of a fungal stroma on the flowering culms ('choke disease') of the host. However, the degree of effect on host reproduction varies with species. In mutualistic associations, that is, in some *Epichloë* spp. that do not cause choke disease, the endophyte grows systematically within its host (Fig. 1), including the developing seeds (Fig. 2), and is entirely dependent on the survival and growth of the grass host plant for its own growth.

It is believed that fungal endophytes of grasses have two modes of reproduction. The sexual species of genera *Epichloë* and *Balansia* can be horizontally transmitted through development of ascospores. Because *Epichloë* species are obligately outcrossing ascomycetes, development of the sexual spores is dependent upon transfer of spermatia of one mating type to an unfertilized stroma of the opposite mating type occurring on different individuals of the host plants. Transfer of spermatia of *Epichloë typhina* (Pers.) Tul. & C. Tul. is accomplished by flies of genus *Botanophila* (Anthomyiidae; Diptera), which visit stromata for feeding and oviposition. Immediately after cross-fertilization of the fungus, perithecia begin to develop on the stroma. During flowering of the host plant, the ascospores produced within the perithecia of infected individuals in the population are forcibly ejected. The ascospores, possibly dispersed by air currents, may land on another healthy grass plant and may initiate infection. In contrast,

Fig. 1 Endophytic convoluted hypha of *Epichloë coenophiala* (Morgan-Jones & Gams) C.W. Bacon & Schardl. in a culm-scrapping preparation from *Festuca arundinacea* Schreb. ($\times 1600$).

Fig. 2 Four-week-old culture of *Epichloë typhina* subsp. *poae* (Tadych, K.V. Ambrose, F.C. Belanger and J.F. White) Tadych from seeds of *Poa secunda* subsp. *juncifolia* (Scribn.) Soreng grown on potato dextrose agar at room temperature ($\times 0.7$).

many sexual *Epichloë* species and all of their asexual mutualistic species are typically transmitted vertically from maternal plants to their offspring. For most of their life cycle the endophytes inhabit, asymptotically and systemically, the apoplasts of the aboveground organs of infected host plants, including the embryos of viable seeds, and can be disseminated vertically to successive generations of the host plant. Infected seeds and vegetative tillers of infected host plants are the only known modes of propagation of these endophytes. Additionally, several *Epichloë* spp., such as *Epichloë festucae* Leuchtm., Schardl & M.R. Siegel, are represented by species that have a remarkable mixed-transmission strategy, that is, horizontal and vertical transmission modes. In these cases, some tillers produce stromata while other tillers on the same plant are asymptomatic and produce normal, vigorous, endophyte-infected seeds.

During the last decade some *Epichloë* endophytes have been also shown to emerge from plants and produce a network of mycelium, conidiophores, and conidia on the surfaces of plants (Fig. 3). This epiphyllous mycelium is most evident on leaf blades of certain species of the Pooideae, including the bent grasses, fescues, forest hedgehog grass, ryegrasses, wild barley, and some blue grasses. The epiphyllous conidia are viable and spread via water currents, rain splash, or drip splash to adjacent plants. It is likely that epiphyllous conidia are responsible for some of the parasexual recombination 'hybridization' that may occur in the *Epichloë* endophytes.

In addition to the e-endophytes a number of other seed-transmitted grass fungal endophytes have been described. Certain cool-season grasses harbor nonclavicipitaceous fungal endophytes that are less frequent than e-endophytes. These fungi belong to two different groups, that is, p-endophytes and a-endophytes. The p-endophytes include *Gliocladium*- and *Phialophora*-like endophytes ('p' for penicillate disposition of conidiophores, common to *Gliocladium*-like and *Phialophora*-like fungal species) that can be isolated from culms and seeds of numerous festucoid grasses, for example, from perennial ryegrass (*Lolium perenne* L.), tall fescue (*Festuca arundinacea*), meadow fescue (*Festuca pratensis* Huds.), Arizona fescue (*Festuca arizonica* Vasey), and giant fescue (*Festuca gigantea* (L.) Vill.). These endophytes are represented by species of the order Eurotiales (Ascomycota). The a-endophytes is a group of grass endophytes found in Italian ryegrass (*Lolium multiflorum* Lam.), other annual species of the *Lolium* genus, and *Festuca paniculata* (L.) Schinz & Thell. The a-endophytes belong to parasitic species of *Acremonium* similar to *Acremonium chilense* Morgan-Jones, J.F. White & Piont. (Hypocreales; Ascomycota), an endophyte of orchard grass (*Dactylis glomerata* L.). At present, the ecological and physiological importance of p- and a-endophytes of grasses are not determined or understood.

Fig. 3 Epiphyllous growth of *Epichloë typhina* subsp. *poae* on a two-week-old *Poa secunda* subsp. *juncifolia* seedling ($\times 3$).

The warm-season grass, *Trichachne insularis* (L.) Nees, was found to harbor a nonclavicipitaceous, seed-transmitted endophyte identified as *Ramulispora trichachnicola* (J.F. White & Morgan-Jones) U. Braun, an anamorphic species of genus *Mycosphaerella* (Mycosphaerellaceae; Ascomycota). Another seed-transmitted fungus *Gibberella fujikuroi* (Sawada) Wollenw. (Nectriaceae; Ascomycota) has been isolated from maize (*Zea mays* L.), sorghum (*Sorghum* spp.), and other plants in the Poaceae family as a symptomless endophyte. The horizontally transmitted entomopathogenic fungus *Beauveria bassiana* (Bals.-Criv.) Vuill. (Clavicipitaceae; Ascomycota) is also known to form an endophytic association with maize.

Nonsystemic grass endophytes present another group of fungal endophytes. At present, little is known about nonsystemic endophytic fungi that inhabit grass species. Most studies of grass endophytes have focused on systemic endophytes. However, some studies indicate that in addition to systemic infections, endophytes that form localized infections in grasses may be also diverse and widespread. Generally, dominant nonsystemic grass endophytes are represented by the genera *Alternaria*, *Cladosporium*, *Epicoccum*, *Fusarium*, *Phoma*, and pathogens typical of grass hosts. Because of their mode of dissemination, diversity and dispersion of this group of grass endophytes is probably more variable than that of systemic grass endophytes and depends on availability and viability of spores of the fungus.

Some common endophyte–grass associations

Tall fescue – *Epichloë coenophiala* association

Tall fescue (*F. arundinacea* = *Lolium arundinaceum* (Schreb.) Darbysh.) is one of the best-known examples of a grass with an endophyte that causes toxicity. The grass was brought to the United States from Europe in the late 1800s. It was officially discovered in Kentucky in 1931, tested at the University of Kentucky, and released in 1943 as ‘Kentucky 31’. From the mid-1940s it became popular with farmers, spreading quickly throughout the midwestern and southern United States. Today it accounts for well over 16 million hectares of pasture and forage land in the United States. The problem of livestock neurotoxicosis (‘fescue toxicosis’ also known as ‘fescue foot’ or ‘fescue lameness’) became a major concern in the United States. Several studies show that consumption of endophyte-infected tall fescue decreases the feed intake of cattle and therefore lowers animal weight gains. Affected cattle also produce less milk, have higher internal body temperatures and respiration rates, develop a rough hair coat and demonstrate an unthrifty appearance, salivate excessively, have poor reproductive performance, and maintain reduced serum prolactin levels. By the end of the 1970s, the association of this toxicity with the endophyte had been discovered. The endophyte was originally identified as a strain of *E. typhina*, but was later described as *E. coenophiala*. *E. coenophiala* produces several alkaloids, particularly, the alkaloid ergovaline that is structurally related to ergotamine, a major factor in ergot poisoning due to ingestion of *Claviceps purpurea* (Fr.) Tul. ‘ergots’ contaminating rye flour.

Perennial ryegrass – *Epichloë festucae* var. *lolii* association

Perennial ryegrass (*L. perenne* L. subsp. *perenne*) is a valuable forage and soil stabilization plant. In New Zealand the neurotoxic disease ‘ryegrass staggers’ (also known as ‘perennial ryegrass staggers’) of sheep and cattle has long been reported and attributed to the consumption of perennial ryegrass. In 1898 for the first time the presence of a fungal endophyte in the seeds of *L. perenne* was observed, and 40 years later the endophytic fungus from *L. perenne* was isolated and grown in agar culture. The association between the *L. perenne* endophyte and ‘ryegrass staggers’ was finally established in 1981. *Epichloë festucae* var. *lolii* (Latch, M.J. Chr. & Samuels) C.W. Bacon & Schardl that infects perennial and hybrid ryegrasses was shown to synthesize several alkaloids. Three of these are known to be particularly important to pasture management, specifically (1) lolitrem B, a tremorgenic molecule responsible for livestock ‘staggers’, (2) ergovaline, an ergopeptide that has vasoconstrictive effects and causes heat stress in grazing animals, also responsible for ‘fescue toxicosis’, and (3) peramine, a tripeptide that deters some insects, particularly the Argentine stem weevil, from feeding on ryegrass but is not toxic to mammals. Perennial ryegrass staggers is a very serious problem for grazing livestock (sheep, cattle, horses, deer) in New Zealand; however, mortality rates are generally low. Ryegrass staggers occur sporadically in North and South America, Europe, and Australia.

Darnel ryegrass – *Epichloë occultans* association

Darnel ryegrass = darnel (*Lolium temulentum* L.) is another common endophyte-infected grass species. This species has a long-recorded history as a plant poisonous to humans and animals. Darnel was known as a weed and as a poisonous plant in earlier times. The earliest written references to darnel indicating it to be a noxious and toxic weed that caused problems for humans and animals may be found in the Gospel of Matthew of the New Testament and in authors such as Plautus, Virgil, Ovid, Dioscorides, and Shakespeare. Darnel seed from 4000-year-old archeological materials in ancient Egypt contained endophyte mycelium. It was generally understood that human beings would be poisoned by ingestion of flour or baked products containing seeds of darnel as a contaminant. Contamination was also undesirable because of the strong taste of darnel seeds, which, for example, resulted in inferior bread. Darnel seeds were sometimes added to beer as a flavoring. By the end of the 1800s it was discovered that a fungus infects seeds of darnel. Currently we know that darnel seeds contain an endophytic fungus, and this symbiotic fungus is known as *E. occultans* (C.D. Moon, B. Scott & M.J. Chr.) Schardl.

The sleepygrass – *Epichloë chisosae* association

Sleepygrass (*Achnatherum eminens* (Cav.) Barkworth) is a perennial grass forming stout, erected clumps in dry plains, hills, and open woods. The grass is native to North America, and is abundant in southwestern United States. It was found to be toxic and narcotic to grazing animals, that is, to horses, cattle, and sheep. Animals, after consumption of relatively small quantities of the

grass, go to sleep for 2–3 days, and then gradually recover. Ergot alkaloids, that is, ergonovine, ergonovinine, lysergic, and isolysergic acid amides, have been identified as the sleep-inducing agents in sleepygrass. These alkaloids are produced by *E. chisosae* (J.F. White & Morgan-Jones) Schardl, the endophyte isolated from this plant and related species of the genus. However, recent studies suggest that the level of ergot alkaloids in native sleepygrass populations may be highly variable within and among populations despite the level of endophyte infection. Animal toxicity is localized in particular areas where particular strains of the endophyte may predominate.

The 'drunken horse grass' – *Epichloë* association

Drunken horse grass (*Achnatherum inebrians* (Hance) Keng) is a perennial bunchgrass, distributed on alpine and subalpine grasslands of northwestern China and Mongolia. Horses that have grazed *A. inebrians* develop a stagger; the animals walk as if drunk, with some being unable to stand after falling. The symptoms persist for 6–24 h, and usually they appear to be completely recovered after 3 days. Severely affected animals die within 24 h of consumption of the grass. Toxicity of *A. inebrians* was reported by Marco Polo and the Russian explorer Nikolai Mikhaylovich Przhevalsky. In the last decade the presence of two endophytes, *E. gansuensis* (C.J. Li & Nan) Schardl and *E. inebrians* (C.D. Moon & Schardl) L. Chen & C.J. Li, in this grass species was confirmed. In the study of alkaloid content, it was found that infected *A. inebrians* had two major toxic alkaloids: ergonovine and lysergic acid amide.

The 'dronkgras' – *Epichloë* *melicicola* association

Staggers grass = 'dronkgras' (*Melica decumbens* (L.) Weber) is a tufted perennial, very coarse grass with usually rolled and very rough leaves. *M. decumbens* is endemic to Africa and has a limited distribution in South Africa, being found only in the arid areas of central South Africa. It grows amongst rocks, under trees, and shrubs on hill- and mountainsides, occasionally in areas along roadsides. The name 'staggers grass' comes from the fact that this grass has narcotic effects on cattle, horses, donkeys, and sheep. The tremorgenic neurotoxins produced by the endophyte *E. melicicola* (C.D. Moon & Schardl) Schardl were found to be responsible for the narcotic effect of *M. decumbens* on grazing livestock. Usually, consumption of grass is not lethal and the animal recovers. This is probably because the leaves of the grass are very coarse, and animals do not graze it frequently, except when the grass is very young.

Forest hedgehog grass – *Epichloë* association

Forest hedgehog grass (*Echinopogon ovatus* (G. Forst.) P. Beauv.) is a tufted perennial, mesophytic grass often found in moist forested areas (in wet sclerophyllic woodlands and by creeks). The grass is endemic to Australia, New Guinea, New Zealand, and Tasmania. Young plants of *E. ovatus* cause 'staggers', sometimes known as 'wobbles' in stock. The grass was found to harbor endophytes *Epichloë aotearoae* (C.D. Moon, C.O. Miles & Schardl) Leuchtm. & Schardl and *Epichloë australiense* (Moon & Schardl) Leuchtm. The presence of indole-diterpenoid and loline alkaloids in endophyte-infected *E. ovatus* was confirmed.

'Huecú' grasses – *Epichloë* *tembladerae* association

Poa huecu Parodi and several other grasses of South America (e.g., *Festuca argentina* (Speg.) Parodi, *Festuca hieronymi* Hack., *Festuca magellanica* Lam., *Festuca superba* Parodi ex Türrpe, and some other *Bromus* spp., *Melica* sp., *Phleum* spp. and *Poa* spp.) are colonized by the endophytic fungus *E. tembladerae* (Cabral & J.F. White) Iannone & Schardl. The association of the endophyte with *F. hieronymi* and *P. huecu* is probably responsible for toxicosis syndromes, called 'tembladera' or 'huecú' in grazing animals. 'Tembladera' is from the Spanish word that means 'tremble', and word 'huecú' is from the indigenous Araucanian language of the tribes that lived in the region and means 'intoxicator'. Huecú toxicosis results from consumption of *P. huecu* and is frequently lethal to animals. Studies on *E. tembladerae* suggest that toxicity of the infected grasses to mammals is associated with the ergot alkaloids, lolitrem, and some glycoproteins, produced by the fungus.

Locoweed and Poison Pea Endophytes

The name locoweed is derived from Spanish 'loco', which means insane or crazy. In English, the term loco has been used by the people of North America for over a century to describe an unusual behavior and neurological syndrome of grazing animals poisoned by certain legumes (Fabaceae). These certain legume species in the related genera of *Astragalus*, *Oxytropis*, commonly known as 'locoweeds' or 'milkvetch', and *Swainsona*, known as 'poison peas', may be found in semiarid regions of Asia, the Americas, Europe, North Africa and Australia. Both wildlife and livestock animals that feed on these plants exhibit similar neurological syndromes, called 'locoism' in North America or 'pea struck' in Australia, characterized by weight loss, altered behavior, depression, decreased libido, infertility, abortion, birth defects, and death.

The mechanism of toxicity caused by these plants has been explained decades ago by isolation of the indolizidine alkaloid, swainsonine (Fig. 4) from *Swainsona canescens* (Benth.) F.Muell. (Darling pea), a legume native to Australia, and isolation of swainsonine N-oxide from *Astragalus lentiginosus* Douglas (spotted locoweed or freckled milkvetch). For years, it was thought that swainsonine was a plant-derived secondary metabolite, however, in fact, it was first isolated from a fungus, not a plant. Recently, it was shown that endophytic fungi associated with the *Astragalus*, *Oxytropis*, and *Swainsona* plants produce swainsonine that intoxicates animals, and deters many herbivores from consuming the plants. Although numerous species within each of the three genera are colonized by fungal endophytes and reported to contain swainsonine, many other species are endophyte-free, thus nontoxic to the animals.

Fig. 4 Swainsonine.

All swainsonine-containing locoweeds/milkvetches and poison peas investigated thus far are associated with endophytes belonging to *Alternaria* spp. section *Undifilumi* (Pleosporales; Ascomycota). Mycelia of the endophytic fungi systematically colonize the parts of the host, which are aboveground, i.e., stem, leaf, inflorescence, and seed, but cannot be found in underground parts. In the seed the mycelia are primarily found in the seed coat, but are not present in the embryo. The endophytes are vertically transmitted from seed to progeny. Until now the following endophytic species, i.e., *Alternaria oxytropis* (Q. Wang, Nagao & Kakish.) Woudenb. & Crous, *Alternaria cinerea* (Baucom & Creamer) Woudenb. & Crous, and *Alternaria fulva* (Baucom & Creamer) Woudenb. & Crous have been isolated from the locoweed/milkvetch and poison pea plants, and identified to produce swainsonine.

Marine Endosymbionts

The marine environment may offer a variety of unexplored endosymbiotic microorganisms. Due to the complicated nature of marine symbiotic associations and experimental limitations, the ecology and chemistry of these interactions has not been well studied. Only in a few cases a specific microbe–host relationship, for example, symbiosis or permanent association, has been proven. Most of the literature reports describe the sporadic occurrence of variable microorganisms for certain hosts. Mostly bacteria but also fungi are to be found in marine animals and algae as epi- and endobionts. However, marine fungi are not taxonomically well defined. In general, the marine environment includes obligate marine fungal species, which are considered to be fungi that grow and sporulate exclusively in a marine habitat. It also includes facultative marine fungi, that is, those that can be isolated from both terrestrial and marine environments, and are adapted to and isolated from various marine habitats, like near-shore or estuarine environments. Marine fungi that do not germinate in the natural marine habitat are not included in these groups. One of the better-documented relationships between marine derived fungi and other marine organisms is the fungal–algal symbiotic association ‘mycophycobiosis’. It was estimated that one-third of all known marine fungi are associated with marine algae and these fungi reside inside the algal tissues. Studies of marine-derived fungi indicate the enormous diversity of the fungal community in the world’s oceans and their biochemical uniqueness.

Ecological Impacts of Endophytes

Abiotic and biotic stresses due to noninfectious and pathogenic plant diseases, pests, and unfavorable growing conditions are major causes for plant productivity losses. Productivity of cultivated plants relies heavily on high chemical inputs. Recently, natural and biological control of diseases and pests affecting cultivated plants has gained much attention as a way of reducing the use of chemical products in agriculture. Biological control offers an alternative or supplement to chemical pesticides in plant protection. This approach incorporates one or more organisms to maintain another pathogenic organism below a level at which it is no longer an economical problem. Use of endophytic organisms could enhance plant growth and productivity on a worldwide basis.

Some groups of endophytic microorganisms have been described as ‘defensive mutualists’ that protect host plants against biotic and abiotic stresses. In return, the endophytic symbionts acquire nutrients from their host plants. Endophytic arbuscular mycorrhizal fungi, which live in mutualistic symbiosis with at least 80% of plants, effectively protect host plant from many root diseases, reduce infection by nematodes, increase stress tolerance like drought resistance, tolerance to heavy metals and salinity, and increase phosphorous uptake in phosphorous-deficient soils. Endophytes of upper parts of grasses and other plants also benefit their hosts. The benefits frequently reported include systemic resistance against pathogens, reduced herbivory, increased drought resistance, improved tolerance to heavy metals, and generally enhanced growth and an increase in the plant’s fitness to environmental extremes. The fungal endophytes may also influence the plant pathogen assemblages, and reduce their diversity and abundance. For example, in *F. arundinacea*, endophyte infection reduced seedling blight caused by *Waitea circinata* Warcup & P.H.B. Talbot and crown rust caused by *Puccinia coronata* Corda relative to endophyte-free plants, but colonization by *E. coenophiala* did not affect rust caused by *Puccinia graminis* Pers. Also, *Alternaria* leaf spot caused by *Alternaria triticina* Prasada & Prabhu was significantly more common on endophyte-free *Panicum agrostoides* Spreng. than on plants with endophyte. Endophyte-infected grasses may also experience a lower incidence of disease when insects, vectors of plant pathogens, are deterred by endophytes. Although the ecological roles played by endophytic fungi are more diverse and varied, these benefits arise in part from the

production of fungal metabolites (usually alkaloids) by the endophyte or endophyte–plant complex. However, in some cases the mechanisms of defense are not fully understood and require further study.

In contrast, in horizontally transmitted endophytes associated with photosynthetic tissues such as leaves of nongrass plants, the benefits are less clear. Generally, these endophytes are believed to also function as defensive mutualists of host plants; however, in most cases their ecological roles have not been assessed experimentally. Recently, several studies have provided evidence for important roles of endophytes in enhancing plant defenses against biotic stresses, such as protection from herbivores, pathogenic fungi, nematodes, and neighboring plants' competition, and abiotic stresses. Recent studies have shown that the endophyte *Trichoderma ovalisporum* Samuels & Schroers that colonized stems and fruits of *Theobroma gileri* Cuatrec. has the ability to parasitize and antagonize the necrotrophic mycelium of pathogenic *Moniliophthora perniciosa* (Stahel) Aime & Phillips-Mora, and *Moniliophthora roreri* (Cif.) H.C. Evans, Stalpers, Samson & Benny. Another study showed that seedlings of *Theobroma cacao* L. inoculated with seven endophytic fungal species and exposed to *Phytophthora* spp., species that are pathogens of the plant, were more resistant than endophyte-free plants. Leaves of the control endophyte-free plants died in greater numbers and suffered much more pathogen damage than endophyte-infected plants. Also, the relative benefit of endophyte inoculation was higher in older than in younger leaves.

Endophytic fungi contribute to and may also be responsible for the adaptation of host plants to environmental stresses. For example, the heat-tolerant perennial panicgrass (*Dichanthelium lanuginosum* (Elliott) Gould) is symbiotic with a fungal species of the genus *Curvularia*. The endophytic fungus was isolated from the grass collected from geothermally heated soils of Yellowstone National Park (Wyoming, Montana, and Idaho, USA) and Lassen Volcanic National Park (California, USA). Geothermal soils of Yellowstone and Lassen Volcanic National Parks may reach temperatures as high as 57°C, and on an annual basis the grass is exposed to high temperatures as well as periods of drought conditions. Laboratory and field studies conducted by Rusty Rodriguez (US Geological Survey/University of Washington), Regina Redman (US Geological Survey/University of Washington), and Joan Henson (Montana State University) have shown that the endophytic fungus confers thermotolerance to the host plant and that this fungal–plant association is responsible for survival of both species in geothermal soils. When these organisms were grown asymbiotically under controlled conditions, the maximum growth temperatures of *D. lanuginosum* and *Curvularia* sp. were 40 and 38°C, respectively; while with the endophyte plants grew at considerably higher temperatures. Another example is the fungus *Piriformospora indica* Sav. Verma, Aj. Varma, Rexer, G. Kost & P. Franken originally isolated from a spore of mycorrhizal fungus *Funneliformis mosseae* (T.H. Nicolson & Gerd.) C. Walker & A. Schüßler. Some studies showed that *P. indica* is able to endophytically colonize roots of various crop plants. It has been shown that isolates of *P. indica* in roots of barley plants enhanced development of the host plant and increased grain yield. It was speculated that this endophytic fungus elevated antioxidative status of the infested roots and therefore protected roots from root pathogens like *Fusarium culmorum* (W.G. Sm.) Sacc. and *Bipolaris sorokiniana* (Sacc.) Shoemaker. Also, the systemic plant response, as a result of induced resistance by the endophyte, causes a reduction of powdery mildew (*Blumeria graminis* (DC.) Speer) infection of barley leaves. The fungus also protects the barley plants from salt stress.

Production of Nontoxic Endophytes

It is also well documented that endophytic fungi have been implicated in toxicity of some poisonous plant species. Grass fungal endophytes are a particularly important group of fungi that have been found to naturally produce a range of mycotoxins, alkaloids, and physiologically active chemical compounds. Some of these substances cause problems for livestock and are recognized as, for example, the causative agents of economically important livestock toxicoses, such as 'fescue toxicosis' and 'ryegrass staggers'. It has been found that some endophytes of ryegrasses and some other related grass species have reduced toxicity to grazing livestock while at the same time they enhance tolerance to pests and/or abiotic stresses. It has also been discovered that some toxic and beneficial alkaloids have separate biosynthetic pathways, allowing the selection or development of endophyte strains that show low animal toxicity but still possess anti-insect qualities. Axenic cultures of selected grass fungal endophytes may be produced and inoculated into seedlings of grasses. The discovery and commercialization of low-toxicity *Epichloë* endophytes along with the technology for their reinoculation resulted in the development of elite grass cultivars that are persistent, productive, and enhance animal performance, for example, Greenstone™ tetraploid hybrid ryegrass with Endosafe™ endophyte, and tall fescue cultivars with MaxQ™ endophyte.

Endophytes as Sources of Bioactive Metabolites

Microorganisms demonstrate many unique characteristics. Among these characteristics is the production of a vast range of biologically active substances and secondary metabolites. Microorganisms are one of the richest resources of biologically active substances and secondary metabolites with novel structures and potential activities. Secondary metabolites, also known as idiolites, have been defined as low-molecular weight and naturally produced substances that often possess chemical structures quite different from primary metabolites, such as amino acids, organic acids, and sugars from which they are produced. Their functions in the producing organisms are not obvious. They are usually hypothesized to function as chemical defenses for the hosts, but may be potential viable weapons against other organisms. In addition, secondary metabolites may be agents of symbiosis and agents of metal transport. Finally, these metabolites may act as sex hormones, plant growth stimulants, and as effectors of differentiation. For

many reasons these compounds may have tremendous economic importance to humankind and an extraordinary impact on the quality of human life. Some fungal secondary metabolites are beneficial (antibiotics such as cephalosporin and penicillin) while others are harmful (carcinogens such as aflatoxin and ochratoxin). The secondary metabolites produced by microbes are generally large and complex chemicals that are not readily synthesized using recombinatorial synthetic approaches. However, a number of drugs derived from fungal metabolites have been developed as their modified analogs. Antibiotics, antifungal, anticancer, immunosuppressive agents, and hypocholesterolemic agents that are derived from fungal compounds have been used for over 50 years.

During the last three decades the fungi living internally in living tissues of plants have been targeted as valuable sources of new bioactive compounds and they have become a mainstay of natural product screening programs. Growth of endophytic fungi within hosts without causing apparent disease symptoms and metabolic interaction of endophytes with hosts may favor the synthesis of biologically active secondary metabolites. According to a study performed by Barbara Schulz (Technical University of Braunschweig) and her colleagues, the proportion of novel structures produced by endophytic isolates (51%) was considerably higher than that produced by soil isolates (38%). Among the fungal genera, endophytic fungi from *Acremonium*, *Chaetomium*, *Colletotrichum*, *Fusarium*, *Pestalotiopsis*, *Phoma*, and *Phomopsis* are known to produce bioactive compounds of medical importance. In addition, endophytic fungi growing in axenic culture can also produce biologically active compounds, including several alkaloids, antibiotics, and plant growth-promoting substances. However, the amount and kind of compounds that are produced by a fungus will be affected by factors like temperature, degree of aeration, and the composition of the medium used for culturing. Some endophytic fungi have been identified as sources of anticancer, antidiabetic, and immunosuppressive compounds. For example, anticancer molecule paclitaxel (Taxol, Fig. 5), originally discovered in the bark of the Pacific yew tree (*Taxus brevifolia* Nutt.), has also been found to be produced by the endophytic fungus *Taxomyces andreanae* Strobel, Stierle, Stierle & Hess. Another endophytic fungus *Muscodora albus* Worapong, Strobel & Hess has an ability to produce a mixture of volatile organic compounds (VOCs) that were fatal to a wide variety of human- and plant-pathogenic fungi and bacteria.

Endophytic fungi are also more often recognized as a group of organisms capable of providing a source of novel bioactive compounds and secondary metabolites for biological control in agriculture as well as for biotechnology and industrial applications. It was shown that production of herbicidally active substances by endophytic fungi is 2 and 3 times higher than phytopathogenic fungi and soil fungi, respectively.

Endophytic fungi play an increasingly important role in the integrated pest management programs in agriculture. Many of the secondary metabolites produced by *Epichloë* grass endophytes significantly increase deterrence of vertebrate herbivores, insects, and nematode pests. It has been demonstrated that the secondary metabolites produced by the fine fescue endophyte *E. festucae* are inhibitory to other fungi. It has also been shown that endophyte-infected grasses contain a range of biologically active compounds

Fig. 5 Paclitaxel (Taxol).

that either are derived from endophyte or are produced as a result of the association. Four main classes of defensive compounds have been associated with endophyte presence in grasses and the following effects have been described.

Ergot Alkaloids

Ergot alkaloids cause toxicoses in grazing mammals with a range of symptoms from stupor and appetite suppression through reproductive problems and dry gangrene to death. The ergot alkaloids (Fig. 6) are produced by a wide range of filamentous fungi, primarily by members of the Clavicipitaceae family, including the above-mentioned grass endophytes of the genera *Epichloë* and the genera *Claviceps* and *Balansia*.

Indole-diterpene metabolites

Indole-diterpene metabolites produce a number of biological effects, including anti-insect activity (feeding deterrence, modulation of insect receptors functions, toxicity) and mammalian tremorgenic activity (staggers). Indole-diterpenoides (Fig. 7) have been reported from *Epichloë* as well as from some fungi of the genera *Claviceps*, *Aspergillus*, and *Penicillium*.

Peramine

Peramine is an unusual pyrrolopyrazine, and is produced by most *Epichloë* endophyte species symbiotic with grasses (Fig. 8). It is a metabolite that has specific biological activity as an insect feeding deterrent. Peramine is deterrent to invertebrate herbivores, especially the Argentine stem weevil, and is also active in preventing feeding activity of aphids, but is not toxic to mammalian herbivores.

Fig. 6 Ergot alkaloids: (a) lysergic acid, (b) ergonovine, and (c) ergovaline.

Fig. 7 Indole-diterpene: Lolitrem B.

Fig. 8 Peramine.

Lolines

Lolines are classified as pyrrolizidines, a class that also includes plant alkaloids known for their insecticidal activity (Fig. 9). These substances are insecticidal alkaloids with insect-deterrent activities, possessing little or no activity against large mammals. Lolines are neurotoxic to a broad range of insects, and when produced by endophytes in plants they have been shown to defend the plants from aphids. Lolines are only known from endophyte-infected grasses, and plants of the genus *Adenocarpus* (Fabaceae) and *Argyrea*

Fig. 9 Loline.

Fig. 10 Auxin – 3-indoleacetic acid (IAA).

mollis (Burm.f.) Choisy (Convolvulaceae). It is possible that undiscovered fungal symbionts might be responsible for loline production in *Adenocarpus* and *Argyrea* species.

Many, but not all, *Epichloë* species produce up to three classes of these alkaloids. In addition to the above, several simple indole alkaloids have been isolated from cultures of endophytic fungi; these include the simple auxins, for example, 3-indoleacetic acid (IAA, Fig. 10) and the indole glycerols, for example, 3-indolylbutanetriol.

Reports of the secondary metabolites from true marine endophytes are relatively rare. This may be due to the relative difficulty in collecting and culturing of marine endosymbionts and their usually slow growth in laboratory conditions rather than lack of ability to produce secondary metabolites. In recent years, an increasing number of natural products from marine-derived fungal endophytes have been reported. Described below are some examples of secondary metabolites from marine-derived endophytic fungi. Isolated from the green alga *Enteromorpha* sp., the endophytic fungus *Wardomyces anomalus* F.T. Brooks & Hansf. (Microasaceae; Ascomycota), collected around Fehmarn island in the Baltic Sea, showed (1) antimicrobial effects of the crude extract toward *Microbotryum violaceum* (Pers.) G. Deml & Oberw. and *Aspergillus repens* (Corda) Sacc. and (2) inhibition of HIV-1 reverse transcriptase (HIV-1-RT). Investigation of the extract yielded several xanthone derivatives. Xanthones are a unique class of biologically active compounds possessing numerous bioactive capabilities, such as antimicrobial, antitubercular, antitumor, antiviral, and antioxidant properties. Xanthone derivatives occur in a number of higher plant families and fungi. Some fungal species are well known as sources of xanthone derivatives, for example, *Penicillium raistrickii* G. Sm., *Phomopsis* sp., *Actinoplanes* sp., *Ascodesmis sphaerospora* W. Obrist, and *Humicola* sp. The cultivation of the marine fungus *Arthriniium arundinis* (Corda) Dyko & B. Sutton isolated from inner tissue of the North Sea alga *Polysiphonia violacea* Grev. led to the isolation of several new secondary metabolites, where some of them exhibited significant cytotoxicity against human cancer cell lines. From the green alga *Ulva* sp., the endophytic and obligate marine fungus *Stagonosporopsis salicorniae* (Magnus) Died. was isolated. This fungus was found to produce, among others, the unusual tetramic acid-containing metabolites ascosalipyrrolidinones A and B. Ascosalipyrrolidinone A has antiplasmodial activity toward (1) strains K1 and NF 54 of *Plasmodium falciparum* Welch (causing malaria in humans) and (2) general antimicrobial activity. Penostatins, new cytotoxic agents toward leukemic cell lines, were reported from a *Penicillium* sp., inhabiting the marine environment and originally isolated from the marine alga *Enteromorpha intestinalis* (L.) Nees. Antimicroalgal substances, halymecins, were isolated from *Fusarium* and *Acremonium* spp. isolated from a marine alga *Halymenia dilatata* Zanardini.

Conclusion

Endophytic microbes are relatively common in all families of plants from polar to tropical regions. The endosymbionts have in several cases proven to play defensive roles in the ecology of host plants. Relatively little is known about the relationships between microbial endophytes and their hosts, especially with respect to chemical ecology. Nonetheless, some observations suggest the importance of the host as well as the ecosystem in influencing the general metabolism of endophytic microbes. Although endophytes are still a poorly investigated group of organisms, with the exception of the clavicipitaceous endophytes of grasses, many studies have proven that they are relatively rich and promising sources of bioactive and chemically novel compounds with a wide variety of potential uses in medicine, agriculture, and industry.

Glossary

Aerobic respiration The energetically downhill electron transfer from a donor molecule or ion to oxygen, which is reduced to water, with concomitant coupled ion, usually proton, translocation and thus, generation of an electrochemical gradient.

Anaerobic respiration The energetically downhill electron transfer from a donor molecule or ion to a molecule other than oxygen, or to an ionic species, with concomitant coupled ion (proton) translocation and, thus, generation of an electrochemical gradient. The reduction products of the acceptors can either be released from the cell or, sometimes, used as further electron acceptors.

Antipport The transport of a molecule or ion up its chemical or electrochemical gradient with the concomitant movement in the opposite direction, but down its electrochemical gradient, of one or more protons or other e.g. sodium ions.

Bacteriorhodopsin A protein of the cytoplasmic membrane of the halophilic archaeobacterium *Halobacterium salinarum* (formerly *halobium*) that has a covalently attached retinal molecule. Absorption of light by the latter pigment results in proton translocation across the membrane.

Chemiosmotic mechanism The transduction of energy between two forms via an ion electrochemical gradient (usually of protons, but sometimes of sodium) across a membrane. Examples of such membranes are the cytoplasmic membranes of bacteria, the inner mitochondrial membranes of eukaryotes, and the thylakoid membranes of plants.

Cytochrome Hemoprotein in which one or more hemes is alternately oxidized and reduced in an electron transfer process.

Electrochemical gradient The sum of the electrical gradient or membrane potential ($\Delta\psi$), and the ion concentration gradient across a membrane (the latter is often defined as ΔpH for protons).

Electron acceptor A low-molecular-weight inorganic or organic compound or an ion – which is reduced in the final step of an electron transfer process.

Electron donor A low-molecular-weight inorganic or organic compound or an ion – which is oxidized in the first step of an electron-transfer process.

Electron transport The transfer of electrons from a donor molecule (or ion) to an acceptor molecule (or ion) via a series of components (a respiratory chain), each capable of undergoing alternate oxidation and reduction. The electron transfer can either be energetically downhill, in which case it is often called respiration, or energetically uphill when it is called reversed electron transfer.

F_oF₁ ATP synthase The enzyme that converts the proton-motive force into the synthesis of ATP. Protons (or more rarely sodium ions) flow through the membrane sector of the enzyme, known as F_o, and thereby cause conformational changes, with concomitant ATP synthesis, in the globular F₁ part of the molecule. Under some circumstances, the enzyme can generate the proton-motive force at the expense of ATP hydrolysis.

Oxidase The hemoprotein that binds and reduces oxygen, generally to water. The name oxygen reductase would better reflect the function.

Oxidative phosphorylation ATP synthesis coupled to a proton or sodium electrochemical gradient, generated by electron transport, across an energy-transducing membrane.

P/O (P/2e) ratio The number of molecules of ATP synthesized per pair of electrons reaching oxygen, or more generally any electron acceptor.

Photophosphorylation ATP synthesis coupled to a proton or sodium electrochemical gradient generated by light-driven electron transport, a process that is often cyclic in bacteria.

Proton-motive force The proton electrochemical gradient ($q.v.$) across an energy-transducing membrane in units of volts or millivolts.

Quinone A lipid-soluble hydrogen (i.e., proton plus electron) carrier that mediates electron transfer between respiratory chain components. The principal types are ubiquinone (under aerobic or anaerobic conditions), menaquinone (usually under anaerobic conditions), and plastoquinone (in plants, but not photosynthetic bacteria). In each case, the reduced form is a quinol.

Redox potential A measure of the thermodynamic tendency of an ion or molecule to accept or donate one or more electrons. By convention, the more negative the redox potential the greater is the propensity for donating electrons and vice versa.

[☆]Change History: November 2014. SJ Ferguson updated the text and further readings to this entire article, added new section on Electron bifurcation, and updated figure legends.

This article is an update of S.J. Ferguson, Energy Transduction Processes, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 123-131.

Respiration The sum of electron transfer reactions resulting in reduction of oxygen (aerobically) or other electron acceptor (anaerobically) and generation of proton-motive force.

Respiratory chain Set of electron-transfer components, which may be arranged in a linear or branched fashion, that mediate electron transfer from a donor to an acceptor in aerobic or anaerobic respiration.

Reversed electron transport The transfer of electrons energetically uphill toward the components of an electron-transfer chain that have more negative redox potentials. Such electron transfer can be regarded as the opposite of respiration, and is driven by the proton-motive force.

Symport The transport of a molecule up its chemical or electrochemical gradient with the concomitant movement, in the same direction but down its electrochemical gradient, of one or more protons or sodium ions.

Uniport The transport of an ionic species in direct response to the membrane potential across a membrane.

Defining Statement

Many microbes obtain energy for growth from either capture of light or oxidation of suitable reductants. This process involves transfer of electrons between proteins of the cytoplasmic membrane (bacteria and archaea) or the inner mitochondrial membrane (eukaryotes). The unifying feature is that the energy is conserved as a proton (sometimes sodium) electrochemical gradient across the membrane. This gradient then drives uphill reactions, notably synthesis of ATP. There are examples of electron transport-independent generation of the gradient. There are also examples of a process known as electron bifurcation in which some electrons flow energetically downhill so as to drive other electrons uphill, in effect a disproportionation reaction.

Introduction

The inner mitochondrial membrane of the eukaryote, the plant thylakoid and the cytoplasmic membrane of the prokaryote (bacteria and archaea) are the key sites where energy available from processes such as the oxidation of nutrients, or from light, is converted into other forms of stored energy that the cell needs. Most prominent among these other forms is ATP and thus these membranes are concerned with oxidative phosphorylation (or photophosphorylation). Energy-transducing membranes share many common components, but most importantly they operate according to the same fundamental chemiosmotic principle. This states that energetically downhill reactions that are catalyzed by the components of these membranes are coupled to the translocation of protons (or more rarely sodium ions) across the membranes. The direction of the movement is outward from the matrix of the mitochondria or the cytoplasm of the bacteria or archaea. The consequence of this translocation is the establishment of a proton electrochemical gradient. This means that the matrix of the mitochondria, or the cytoplasm of the bacteria, tends to become both relatively negatively charged (thus, called the N side) and alkaline relative to the other side of the membranes, the intermembrane space in the mitochondria and the periplasm in Gram-negative bacteria (and equivalent zone in Gram-positive bacteria and archaea), which is thus called the P side (Figure 1). This electrochemical gradient is under most circumstances dominated by the charge term, which means that there is often a substantial membrane potential across the membranes, frequently

Figure 1 (a) Idealized mitochondrion in a eukaryotic cell and (b) Gram-negative bacterium showing the direction of proton translocation linked to an exergonic (energetically downhill) reaction. P represents a relatively positive aqueous phase (i.e., outside the inner mitochondrial membrane or the bacterial cytoplasmic membrane) and N a relatively negative aqueous phase (i.e., inside the mitochondrion (the matrix) or the cytoplasm of a bacterium). represents the ATP synthase enzyme.

estimated to be on the order of 150–200 mV. Under most circumstances, the pH gradient generated by the proton translocation is small, 0.5 unit is an approximate average value. The membrane potential is added to the pH gradient to give the total gradient, which is usually called the proton-motive force if given in millivolts. The conversion factor is such that 0.5 pH unit is approximately equivalent to 30 mV. Strictly speaking, the expression of the gradient as an electrochemical potential requires units of kJ mol^{-1} to be used; in practice, this is rarely done, sometimes causing confusion. I use the term proton-motive force in this article.

Mitochondrial Energetics

The best-known machinery for generating the proton-motive force is the mitochondrial respiratory chain. The standard mitochondrial respiratory chain is found, at least under some growth conditions, in many, but not all, eukaryotic microbes. Diversity is illustrated by yeasts with some species having the classic Complex I (Figure 2) whereas other species have an alternative form of NADH dehydrogenase. The key point is that as a pair of electrons traverses the chain from NADH to oxygen, there are three segments (formerly called sites, but the term is inappropriate because it implies equivalence, and relates to a very old idea that ATP is made at three sites within the electron-transport chain) where protons can be translocated across the membrane. The first and last of these segments effectively move four protons per two electrons, while the middle segment effectively moves only two (Figure 2), but note that this description is an oversimplification. For more details on protein translocation, consult the book by Nicholls and Ferguson mentioned in the 'Further Reading.' Overall, ten protons are moved per two electrons moving along the chain from NADH to O_2 . Electrons may enter the chain such that they miss the first proton-translocating segment of the chain. Succinate and the fatty-acyl CoA intermediates generated during fatty-acid oxidation are the most prominent examples of such electron sources which do not involve the NADH-ubiquinone oxidoreductase (Complex I). Each of these sources delivers electrons to ubiquinone by different enzymes, succinate dehydrogenase or the electron transfer flavoprotein (ETF) in combination with the electron transfer flavoprotein-ubiquinone oxidoreductase (ETF-UQ), respectively. In these cases, six protons are translocated per two electrons. The entry of electrons at the third segment, rare in mitochondria, gives a translocation stoichiometry of four.

The proton-motive force generated can then be used to drive various uphill reactions. Most prominent is ATP synthesis. This is achieved by protons flowing back across the membranes and through the ATP synthase enzyme, often called FoF_1 ATP synthase. Note that in archaea a related enzyme but with some quite distinct features is present and called by analogy the AoA_1 enzyme. There is increasing insight into the mechanism of the ATP synthase enzyme; it functions as a rotary motor in which the flow of protons through the F_o is coupled to rotation and structural changes in the F_1 part of the molecule, events that are linked to ATP synthesis. The number of protons that must pass through the ATP synthase to make one ATP molecule is widely accepted to depend on the number of a certain type of subunit, the c subunit, in the enzyme. An approximate value (see later for further discussion of this point) adopted here for illustration, even though it is not the reality, is three. On the basis of "what goes one way across the membrane must come back the other," it might therefore be thought that the stoichiometry of ATP production per pair of electrons (called the P/O or P/2e ratio) flowing from NADH to oxygen would be $10/3$ (i.e., 3.3) for NADH and $6/3$ (i.e., 2) for succinate. However, matters are a little more complicated. The combined process of entry of ADP and P_i (phosphate) into mitochondria and the export of ATP to the cytoplasm involves the movement of one proton into the matrix (Figure 3). Thus for each ATP made, the predicted stoichiometry is $10/(3 + 1) = 2.5$ for NADH and $6/(3 + 1) = 1.5$ for succinate. These values differ from the classic textbook values of 3 and 2, respectively, but they are now generally accepted. It is intuitive to expect that a cell should seek to maximize the yield of ATP, that is, the P/O ratio. However, such an intuition does not always conform to reality. Thus, many eukaryotic microorganisms possess the 'alternative oxidase,' which is best known in plant mitochondria and allows ubiquinol to be oxidized by oxygen with no associated proton translocation. The energy is instead dissipated as heat. Similarly, *Escherichia coli* lacks Complex

Figure 2 Considerably simplified representation of the proton-translocation stoichiometry, per two electrons, of the mitochondrial respiratory chain. I indicates Complex I (otherwise known as NADH dehydrogenase); III, Complex III (otherwise known as the ubiquinol-cytochrome c oxidoreductase or cytochrome bc_1 complex); IV, Complex IV (otherwise known as cytochrome c oxidase or cytochrome aa_3 oxidase); P, positive aqueous phase; and N, negative aqueous phase. ^aSimplifying has caused some unavoidable inaccuracies (see Nicholls and Ferguson (2013) for accurate detailed description). ^bNote that 2 of the 4H^+ are used to give H_2O .

Figure 3 Charge movement, associated with ATP synthesis and translocation of adenine nucleotides and phosphate across the inner mitochondrial membrane. The stoichiometry of proton translocation through the ATP synthase has in recently commonly been taken to be 3, but this is rarely if ever the actual value which can be non-integral (see text for more information on this point). The translocated protons are not believed to pass through the active site of the ATP synthase enzyme. Note that the adenine nucleotide exchange moves one positive charge into the matrix per nucleotide exchanged and the operation of the phosphate transporter effectively moves the chemical part of the proton (but not the charge) into the matrix. Thus, in combination, the two transporters move one positive charge into the mitochondrion per ATP synthesized and returned to the P phase. Note that these transporters do not operate in bacterial ATP synthesis. This number would be 3 if there are 12c subunits. In practice current knowledge indicates 8 or 10c subunits in mitochondrial ATP synthases.

III and thus fewer protons are translocated as a pair of electrons is transferred from quinol to oxygen compared with an organism in which Complex III is present. There is no general explanation as to why energy is dissipated as heat rather than conserved as a proton-motive force, but the phenomenon implies that under certain circumstances organisms are not 'energy limited' and thus have another priority, for example oxidizing substrates so that the carbon skeletons can be converted into molecules required for the growth of cells. For example, butyrate is more reduced than the average carbon molecule in the cell; thus growth on butyrate often requires dissipation of excess reductant as heat.

The number of protons that must pass through the ATP synthase for a molecule of ATP to be made is uncertain, but is currently thought to vary with the structure of the ATP synthase enzyme in a given organism. It is generally accepted that the mechanism of this enzyme involves the rotation of a circular assembly of one type of subunit (the c subunit), belonging to the F_0 part of the enzyme. A 360° rotation of this assembly drives a similar rotation of a subunit of the F_1 part of the enzyme, which thus interacts sequentially with the three catalytic subunits driving synthesis of three molecules of ATP. The 360° rotation of the assembly in the F_0 part of the enzyme is believed to be driven by the sequential passage of the number of protons that equals the number of c subunits in the assembly. Thus ten subunits, as currently thought to be present in the microbial mitochondrial F_0 , imply a proton to ATP ratio of $10/3 = 3.3$ but 8 in higher eukaryotes and thus $H^+/ATP = 2.66$. In prokaryotes that the number of these subunits varies from 10 to 15, depending on the organism, with variation between 13 and 15 even being seen in different species of cyanobacteria; the proton per ATP ration can thus be as high as 5. In some species such as *Propionigenium modestum* (see later) analogous movement of Na^+ via the circular assembly of c subunits occurs to drive ATP synthesis.

It has been generally thought that eukaryotes are only capable of aerobic respiration. However, there is now evidence of a form of mitochondrial anaerobic respiration in which nitrate is reduced to nitrous oxide (more typically a prokaryotic characteristic, see the following), and of a novel type of mitochondrion in the ciliate protist *Nyctotherus ovalis* that reduces protons to hydrogen. In both these examples, electrons are derived from NADH.

Bacterial Energetics

Many species of bacteria and archaea generate a proton-motive force by a respiratory chain similar to that found in mitochondria. However, there are many types of electron donors and acceptors that can be used by bacteria (eukaryotes are restricted to aerobic oxidative breakdown of reduced carbon compounds), and various forms of anaerobic respiration are widespread. A further general difference between bacteria and microbial eukaryotes is that in the former, the proton-motive force can drive a wider range of functions and be generated in more diverse ways than in the latter. Thus, functions alongside ATP synthesis (for which the enzyme is very similar to that found in mitochondria), such as driving of many active transport processes and the motion of the flagella, are important processes that depend on the proton-motive force in many organisms (Figure 4).

A common mode of active transport is known as the symport; the classic example of this is the lactose-proton symport, coded for by the *lacY* gene of the *lac* operon of *E. coli*, and for which a molecular structure is now available. In this case, a transmembrane protein translocates together a proton down its electrochemical gradient and a lactose molecule up its concentration gradient (Figure 5), but the exact mechanism is presently unknown. There are cases of analogous transporters known where Na^+ is the translocated ion. A second type of transport system is the antiport (Figure 5). Here the movement via a protein of the proton down its electrochemical gradient is obligatorily linked to the movement of another species, typically an ion, in the opposite direction and

Figure 4 The central role of the proton-motive force in linking diverse reactions. Note that the direct generation of proton-motive force from light is unusual, but is exemplified by the proton-pumping bacteriorhodospin protein found in some archaea (halobacteria); a related protein, proteorhodopsin, is found in some bacteria. Normally, light drives electron-transport processes, which in turn generate the proton-motive force.

Figure 5 The three common modes of substrate transport across the bacterial cytoplasmic membrane.

up its electrochemical gradient. Sodium/proton exchange provides an example. The third type, uniport, is the case where an ion moves in direct response to the membrane potential and is rarer than the other two examples in the prokaryotic world.

It is important to appreciate that not all transport processes across the bacterial cytoplasmic membrane are directly driven by the proton-motive force. Some transport reactions are driven directly by ATP. Notable among such systems are ABC (ATP-binding cassette) transporters.

A more subtle aspect of prokaryotic energetics is that in some species of bacteria the proton-motive force must drive reversed electron transport under some circumstances (see later).

A common misconception is that the proton-motive force can be divided between different functions (e.g., 100 mV for ATP synthesis and 50 mV for flagella motion). This notion is incorrect because the proton-motive force across a membrane has a single value at any one time and the magnitude of this force acts simultaneously on all energy-transducing units, be they ATP synthases, active transporters, or flagella.

Principles of Respiratory Electron-Transport Linked ATP Synthesis in Bacteria

In principle, energy transduction on the cytoplasmic membrane is possible if any downhill reaction is coupled to proton translocation. The most familiar examples are probably those that also occur in mitochondria, for example, electron transfer from NADH to oxygen or from succinate to oxygen. In these cases, the electrons pass through a sizeable redox drop (Table 1). In contrast to mitochondria, various species of bacteria can use a wide variety of electron donors and acceptors. The fundamental principle is that the redox drop should be sufficient for the electron transfer to be coupled to the translocation of protons across the cytoplasmic membrane. Table 1 shows that such sizeable drops are associated with the aerobic oxidation of hydrogen, sulfide, carbon monoxide, and methanol, to cite just a few electron donors. Anaerobic respiration is also common with many suitable pairings of reductants and oxidants (e.g., Table 1). Thus, NADH can be oxidized by nitrate, nitrite, nitric oxide, or nitrous oxide. The flow of electrons to these acceptors, each of which (other than nitrate) is generated by the reduction of the preceding ion or molecule, is the process known as denitrification. In *E. coli* under anaerobic conditions, formate is frequently an electron donor, and nitrate and nitrite are the acceptors, with the latter being reduced to ammonia (Table 1) rather than to nitric oxide, as occurs in denitrifying bacteria. A wide variety of electron-transport components, including many different types of cytochrome, are involved in catalyzing these reactions. The mechanisms whereby electron transport is linked to the generation of the proton-motive force are frequently complex. However, nitrate respiration (Figure 6) provides an example of one of the simplest mechanisms that corresponds to Peter Mitchell's original redox loop mechanism feature of his chemiosmotic mechanism.

An important point is that the consideration of the energy drop between the donor and the acceptor (Table 1) is only a guide as to whether proton translocation, and thus ATP synthesis, can occur and, if so, with what stoichiometry. Thus while many bacterial

Table 1 Approximate standard redox potentials^a of some electron-donor and electron-acceptor couples used in respiratory processes

Couple	E° (mV)
$\text{N}_2\text{O}/\text{N}_2$	+1360
$\text{NO}/\text{N}_2\text{O}$	+1180
$\text{O}_2/\text{H}_2\text{O}$	+820
$\text{NO}_3^-/\text{NO}_2^-$	+430
$\text{NO}_2^-/\text{NH}_4^+$	+360
NO_2^-/NO	+350
Fumarate/succinate	-30
Methanol/formaldehyde	-180
NAD^+/NADH	-320
$\text{CO}_2/\text{formate}$	-430
CO_2/CO	-540

Conditions experienced by cells may vary significantly from these and thus the actual redox potentials of the couples should be calculated from the Nernst equation and may differ substantially from those in this table.

^aRedox potential refers to the standard state (1 mol l^{-1} concentrations for solutes and 1 atm pressure for gasses).

Figure 6 A simple mechanism for generating the proton-motive force, the bacterial nitrate reductase system. Oxidation of ubiquinol (UQH_2) to ubiquinone (UQ) on one side of the membrane is accompanied by release of protons to the P side and translocation of the electrons toward the N side, where they combine with protons and nitrate to produce nitrite. Overall, the process effectively translocates two protons per two electrons across the membrane. The mitochondrial electron-transport chain (see Figure 2) involves more complex mechanisms for proton translocation. DH_2 is an unspecified donor to the ubiquinone, and D is the product of oxidizing DH_2 . The crystal structure of nitrate reductase fully confirms the scheme shown here and, in combination with the structure of formate dehydrogenase, shows how a complete redox loop mechanism links oxidation of formate by nitrite to the generation of a proton-motive force (see Further Reading).

species can form a respiratory chain with considerable similarity to that found in mitochondria, others vary from this pattern. Notably all strains of *E. coli* always lack the cytochrome bc_1 complex. Under some growth conditions, it uses cytochrome bo as the terminal oxidase and under others, cytochrome bd . The consequence is that when the former proton-pumping oxidase is operating, eight protons are translocated per pair of electrons flowing from NADH to oxygen, while with the latter oxidase, which does not pump protons but in common with the bo oxidase does effectively move two protons per two electrons as part of the mechanism of reducing oxygen to water, the stoichiometry would be only six. As explained earlier, the corresponding number for mitochondria is ten. This example illustrates the important point that it is not just the energy drop between a donor and an acceptor that is important, but also the details of the components (or molecular machinery) in between. Another example is methanol to oxygen. Periplasmic oxidation of methanol feeds electrons into the electron-transport chain close to the terminal oxidase, yet energetic considerations alone would indicate that electrons could span more proton-translocating sites just as they do when succinate is the electron donor (compare the redox potentials for fumarate-succinate and methanol-formaldehyde, Table 1). A final example to consider is the case in which both the electron donor and the acceptor are in the periplasm and they are connected purely by periplasmic components. In such a case, which applies to methanol (as donor) and nitrous oxide (N_2O as acceptor), the electrons do not pass through any proton-translocating complex. Thus, no proton translocation would occur no matter what the redox drop between the two components.

The electron transport systems can be completely distinct from those in *E. coli*. For example, the cytoplasmic membranes of sulfate-reducing bacteria catalyze electron transfer from hydrogen to APS reductase and sulfite reductase using a quite distinct set of cytochromes.

It is not necessary for electrons to flow over such a large energy drop as they do when they pass from NADH to oxygen (Table 1) to generate a proton-motive force. Thus, if the driving force associated with a reaction is very small, it might still be energetically possible for the passage of two electrons from a donor to an acceptor to cause the translocation of just one proton. If three protons are required for the synthesis of ATP, then the ATP yield would be 0.166 per electron flowing from the electron donor to acceptor. This seemingly bizarre stoichiometry is not only energetically possible but also mechanistically possible because the chemiosmotic principle involves the delocalized proton-motive force that is generated by all the enzymes of the membrane and also consumed by all of them. There is no case known that matches this extreme; nevertheless, there may well be organisms yet to be discovered that have such low stoichiometries of ATP synthesis.

One example of the lowest known stoichiometries of ATP synthesis per pair of electrons reaching the terminal electron acceptor (oxygen) occurs in *Nitrobacter*. Table 1 shows that the redox drop is small between nitrite and oxygen. This organism also illustrates the versatility and subtlety of the chemiosmotic mode of energy transduction. *Nitrobacter* species oxidize nitrite to nitrate at the expense of the reduction of oxygen to water in order to sustain growth. The energy available as a pair of electrons flows from nitrite to oxygen is sufficient to translocate two protons (a more detailed consideration of how this is done is outside the scope of this article). This means, recalling the current consensus that three protons are needed for the synthesis of one ATP molecule, that the ATP yield stoichiometry would be $0.66/2e$. *Nitrobacter* also illustrates another important facet of energy transduction in the bacterial world. The organism is chemolithotrophic, which means that oxidation of nitrite provides not only ATP but also reductant (NADPH), which is required for reducing CO_2 into cellular material. Energetic considerations show that nitrite cannot reduce NADP directly. What happens in the cell is that a minority of the electrons originating from nitrite are driven backward up the electron-transfer system to reduce NAD(P) to NAD(P)H. This is achieved by the inward movement of protons reversing the usual direction of proton movement (Figure 7). This reversed electron-transport process is an important phenomenon in a variety of bacteria, especially those growing in the chemolithotrophic mode.

Most studies of electron transport-linked ion translocation have been carried out with species of bacteria. However, the same fundamental process also occurs in archaea, although with some novel features that reflect some of the extreme growth modes tolerated by these organisms. For example, a key step in methane formation by methanogenic bacteria is electron transfer from hydrogen or the other reductant to a small molecule that contains a disulfide bond. The latter is reduced to two sulfides and the overall process is coupled to the translocation of protons across the cytoplasmic membrane. The proton-motive force thus set up can be used to drive ATP synthesis.

Generation of the Ion Electrochemical Gradient Other than by Electron Transport

ATP Hydrolysis

Organisms that are incapable of any form of respiration still require an ion electrochemical gradient across the cytoplasmic membrane for purposes such as nutrient uptake. One way in which this requirement can be met is by using some of the ATP synthesized by fermentation for ATP hydrolysis by the F_0F_1 ATPase. This means that this enzyme works in the reverse of its usual direction and pumps protons out of the cell. Thus there are many organisms that can prosper in the absence of any electron-transport process, either as an option or as an obligatory aspect of their growth physiology.

Bacteriorhodopsin and Proteorhodopsin

A specialized form of light-driven generation of proton-motive force, and hence of ATP, occurs in halobacteria; these organisms are archaea. The key protein is bacteriorhodopsin, which is a transmembrane protein with seven α -helices, that has a covalently bound

Figure 7 Reversed electron transport illustrated by the example of *nitrobacter*. The majority of electrons is derived from nitrite flow energetically downhill to oxygen via a cytochrome oxidase, which generates a proton-motive force. A minority of electrons is driven energetically uphill by the proton-motive force so as to reduce NAD^+ to NADH. Note that in this diagram no proton stoichiometry values are implied.

retinal. The absorption of light by this pigment initiates a complex photocycle that is linked to the translocation of one proton across the cytoplasmic membrane for each quantum absorbed. Bacteriorhodopsin is one of a family of related molecules. Another, halorhodopsin, is structurally very similar and yet catalyzes the inward movement of chloride ions driven by light. In certain groups of bacteria a protein called proteorhodopsin performs an analogous function to bacteriorhodopsin.

Methyl Transferase

One step of energy transduction in methanogenic bacteria involves an electron-transfer process (see earlier). Another important process in methanogens is the transfer of a methyl group from a pterin to a thiol compound. This exergonic (energetically downhill) reaction is coupled to ion, in this case sodium, translocation across the cytoplasmic membrane.

Decarboxylation Linked to Ion Translocation

In the bacterial world, the electrochemical gradients can be generated by diverse processes other than electron transport or ATP hydrolysis. For example, *Propionigenium modestum* grows by converting succinate into propionate and carbon dioxide. One of the steps in this conversion is decarboxylation of methyl-malonyl coenzyme A (CoA) into propionyl CoA. This reaction is catalyzed by a membrane-bound enzyme that pumps sodium out of the cells, thus setting up a sodium electrochemical gradient (or sodium-motive force). This gradient in turn drives the synthesis of ATP as a consequence of sodium ions reentering the cells through a sodium-translocating ATP synthase enzyme. Apart from illustrating that sodium, instead of proton circuits, can be used for energy transduction in association with the bacterial cytoplasmic membrane, this organism also illustrates that the stoichiometry of ATP synthesis can be less than one per CO_2 formed. It is believed that each decarboxylation event is associated with the translocation of two sodium ions and the synthesis of ATP with three. Thus, nonintegral stoichiometry is consistent with the energetics of decarboxylation and ATP synthesis. This is an important paradigm to appreciate; the underpinning growth reaction for an organism does not have to be capable of supporting the synthesis of one or more integral numbers of ATP molecules.

Metabolite Ion-Exchange Mechanisms

Another example of the generation of a proton-motive force is ion exchange across the membrane. For example, in fermenting bacteria there is evidence that under some conditions an end-product of metabolism, lactic acid, leaves the cell together (i.e., in symport) with more than one proton, resulting in the generation of a proton-motive force (Figure 8). A second example is provided by *Oxalobacter formigenes*, in which the entry of the bivalent anion oxalate is in exchange for the exit of the monovalent formate ion generated by decarboxylation of the oxalate, leading to the net generation of membrane potential (Figure 8). This seems to be the principal mode of generating membrane potential in this organism.

Photosynthetic Electron Transport

Prokaryotic photosynthesis involves a cyclic electron-transport process in which a single photosystem captures light energy and uses it to drive electrons around the cycle (Figure 9). The consequence of this cyclic electron flow is the generation of the proton-motive force. There are two types of photosystem found in prokaryotes. One is related to the water-splitting photosystem that is found in plants; typically this bacterial photosystem is found in organisms such as *Rhodospirillum rubrum*. The second type of photosystem is closely related to the second photosystem of plants, the one that is concerned with the generation of NADPH. *Heliothrix* is an example of an organism carrying this type of center. Plants have both these photosystems, arranged to operate in series. The same is true for the prokaryotic cyanobacteria and the eukaryotic algae.

Figure 8 Two examples of generation of proton-motive force by end-product extrusion from fermenting bacteria.

Figure 9 An oversimplified outline of the cyclic electron-transport process of photosynthetic bacteria. There are two types of reaction centers, depending on the organism. The molecular composition of the system depends on the organism. The two components contribute to the generation of the proton-motive force.

Alkaliphiles

An interesting unresolved problem relates to energy transduction in the alkaliphilic bacteria. The problem is straightforward. These organisms can grow in an environment with a pH as high as 11 or 12. A cytoplasmic pH even as high as 9 means that the pH gradient could be as much as 3 units (equivalent to 180 mV), the wrong way around in the context of the chemiosmotic mechanism. The membrane potential always seems to be larger than 180 mV, but the total protonmotive force can be very low (e.g., around 50 mV). For some organisms that use a conventional proton-translocating respiratory chain and ATP synthase, it is not understood how they survive energetically. In other organisms, there is evidence for the role of a sodium-motive force. This would sidestep the problem of the adverse proton concentration gradient.

Electron Bifurcation

Not all energetically ‘uphill’ reactions in bacteria are driven by the ion electrochemical gradient, important as this is. A process known as electron bifurcation has been recognized in recent years and may prove to be more important in microbial energetics than realized at the time of writing. An example is that of driving electrons uphill in *Rhizobia* from NADH to ferredoxin which in turn can act as the reductant for nitrogen fixation. There is a membrane bound system that can take four electrons from two molecules of NADH and send two on an energetically downhill path to an electron acceptor, in this case oxygen at low concentration. The energy so released can be used to drive a second pair of electrons energetically uphill to reduce two molecules of ferredoxin. The exact enzymology of this process is not fully understood but in energetic terms it can be thought of as similar to a disproportionation reaction in chemistry. Another key role for electron bifurcation is in methanogenesis in organisms lacking cytochromes, whereas in organisms with cytochromes the required uphill reaction is driven by the ion motive gradient. Similarly transfer of electrons from NADH to ferredoxin in some photosynthetic bacteria is driven not by electron bifurcation but by the ion electrochemical gradient using a membrane protein known as Rnf.

Introduction

Entamoeba histolytica is the causative agent of amebiasis, a disease common in developing countries around the world. It causes 100 million cases of disease per year, and was responsible for over 11,000 deaths in 2013 alone, making *E. histolytica* the fourth highest infectious parasite, and the only pathogenic intestinal amoebae. Interestingly, many people come in contact with *E. histolytica* but never develop any symptoms; only 10% of people carrying the parasite develop amebiasis or other symptoms, while the other 90% remain asymptomatic carriers. In both cases, an infectious cyst is ingested from stool with an infectious dose of over 1000 cysts. The nucleus of the cysts then divides through binary fission into eight uninucleated trophozoites in the terminal ileum. The trophozoites then migrate to and colonize the colon where undigested host nutrients and the host microbiota serve as a food source (Fig. 1). In asymptomatic cases, *E. histolytica* remains in the lumen and does not contact the host epithelial cells. The trophozoites re-encyst in the descending colon, recreating the infectious cyst that is excreted in stool and ready to infect a new host. A carrier of the parasite may pass up to 45 million cysts in stool daily. In case of infection, the multitude of parasite virulence factors are able to bypass the host mucosal layer (Table 1), leading to *E. histolytica* contacting the host epithelial cells and causing serious infection such as diarrhea and dysentery, and in some cases extra-intestinal symptoms such as liver granulomas. With such a high rate of infection worldwide, much research has gone into the pathogenesis of *E. histolytica* in the past few decades.

Fig. 1 Life cycle of *E. histolytica*. Mature cysts are ingested by the host, and travel through the gastrointestinal system. In the terminal ileum, the cyst undergoes excystation and gives rise to 4 daughter trophozoites, that migrate to the colon and now capable of causing disease symptoms. The trophozoites may remain in the colon, or may cause extraintestinal disease in the liver, lungs or brain. The trophozoites in the colon eventually undergo encystation and the infectious cyst excreted in stool is now able to infect a new host as the cycle repeats itself.

Table 1 *E. histolytica* virulence factors

Virulence factor	Function
Gal/GalNAc Lectins	binds to Gal/GalNAc of mucus layer to allow adherence and colonization binds to immune cells, facilitating phagocytosis activate macrophage induces host pro-inflammatory response antigenic similarity to host CD59 inhibits complement MAC attack stimulate macrophages to produce TNF- α binds to and activates NLRP3 inflammasome in macrophages binds to complement components C8 and C9 to block the MAC formation
Cysteine proteinases	degrade C-terminal of MUC2 to degrade mucus layer bind to $\alpha v \beta 3$ integrin on goblet cells to induce mucus hypersecretion cleave IgA and IgG degrade cathelicidins cleave C3 activating alternative complement pathway degrade anaphylatoxins C3a and C5a degrade tight junction structures to increase paracellular permeability convert pro-IL-1 β from damaged intestinal cells to active IL-1 β role in liver abscess development
Amoebapores	creates membrane pores in host cell leading to necrosis and apoptosis role in liver abscess development
PGE ₂	disrupt tight junctions by altering claudin-4 disrupt tight junctions by binding to host EP ₄ receptors, inducing a pro-inflammatory response induce neutrophil chemokine IL-8 inhibits Th1 cytokine release, oxidative burst and NO synthesis

History

Since bloody and mucus filled diarrhea are symptoms not unique to amebiasis, early reports of amebic infection are hard to decipher with complete certainty. Those being said, as early as 1000 BCE reports of bloody, mucose diarrhea in the Brigu-samhita, a Sanskrit document, have been located. Later, in 600 BCE, both Assyrian and Babylonian texts describe counts of bloody stool. Similarly, liver and perianal abscesses consistent with amebiasis were described in *Epidemics* and *Aphorisms* in the *Corpus Hippocraticum*. Counts of bloody diarrhea and liver abscesses continued until 16th century when amebiasis was recorded in Europe and Asia among other places, until Europeans colonized the New World and seemingly spread the disease. Intestinal and hepatic amebiasis became even more spread as world trade became more prevalent, making spread of the parasite even easier. Even though these accounts are recognized as amebiasis, it was the book “*Researches into the Causes, Nature and Treatment of the More Prevalent Diseases of India and of Warm Climates Generally*” by James Annersley in 1855 that first distinctly described both intestinal and hepatic amebic infection. It was not until 1857 that the English physician William Budd described the connection between the intestinal disease and liver abscesses. Shortly after in Russia in 1873, as the field of microscopy and germ theory advanced, Friedrich Lösch discovered not only *E. histolytica* itself, but also established the relationship between the parasite and disease from working with a farmer with ongoing dysentery and periods of bloody stool. Descriptions of dysentery and amebic cysts continued to surface over the coming years, solidifying the presence of an infectious dysentery-causing ameba. At the end of the 19th century, William Thomas Councilman and Henry Lafleur definitively described the pathology of amebiasis and first used the terminology “amebic dysentery” and “amebic abscess”, terminology that is still used today in describing amebiasis. In 1925, Emile Brunt suggested that there must be two distinct yet morphologically identical *Entamoeba* species, as not every patient with *Entamoeba* displayed symptoms of amebiasis. In the 1990s, this was proven to be true; pathogenic *E. histolytica* was distinguished from the non-infectious but morphologically identical *E. dispar*.

Morphology and Characteristics

E. histolytica exists as either the infectious cyst or the disease causing trophozoite. The cyst is round in shape and 10–15 μm in diameter. Each cyst contains 4 nuclei, chromatoid bodies and glycogen, and is surrounded by a refractile chitinous wall. The glycogen forms a characteristic vacuole that becomes more diffuse as the cyst matures. The trophozoite is typically pleomorphic in shape and larger in size, ranging from 10 to 50 μm in length and contain usually one nucleus, but up to four nuclei in one trophozoite has been reported. Unlike the cysts, the trophozoites are motile through pseudopodium. TNF- α , fibronectin, the anaphylatoxin C5a and lysed erythrocytes act a chemoattractants of *E. histolytica*. When the parasite chemoreceptors sense one of these stimuli, the cell polarizes and pseudopodia form, allowing the parasite to move. The trophozoites contain chromatoid bodies, glycogen and ingested food including bacteria and red blood cells. *E. histolytica* trophozoites lack classical mitochondria, rough endoplasmic reticulum and a Golgi apparatus, however nuclear bodies including a nucleolus and speckles are present. In both forms, the nuclei are spherical and approximately 4–7 μm in diameter. The nuclei membrane is lined by a single layer of chromatin granules, and contains a 0.5 μm spherical karyosome centrally located in a colorless capsule-like structure. DNA is contained in chromatin, and *E. histolytica* has acetylation, deacetylation and methylation proteins in order to modify chromatin structures and alter gene expression. *E. histolytica* also has a variety of miRNAs, siRNA and sRNA, as well as a functional RNA interference machinery, strongly suggesting iRNA as another method of gene regulation that requires further research.

Although the cyst and trophozoite stages receive the most attention, *E. histolytica* Cyst-Like Structures (CLS) have also been reported. This stage is named for its structural similarities with the cyst, small, rounded, multinucleated structures with a chitin wall. Interestingly, although the CLS resembles the cyst, it shares significantly more proteins with the trophozoite stage. Proteomic analysis has shown that proteins related to stress response were highly abundant in the CLS, whereas metabolic proteins were far less abundant. Based on these characteristics, it is suggested that CLS stages are a rapid trophozoite response to stressful conditions; the chitin wall protects the parasite from perceived threats in the area. Once the danger has passed, the CLS is able to revert back into the trophozoite form.

Amebiasis

The main disease caused by *E. histolytica* infection is termed amebiasis and includes amebic colitis and amebic liver abscesses (ALA). Amebiasis is contracted by ingesting fecally contaminated substances including food and water. After excystation in the terminal ileum or colon, the trophozoites bind to and colonize the host mucus layer. In disease situations, *E. histolytica* then disrupts the protective mucosal barrier, allowing access to the underlying epithelial tissue and invasion occurs. Amebiasis presents as abdominal cramping and pain, watery or bloody diarrhea, and potentially weight loss. Amebic colitis is a rare manifestation, and includes more serious symptoms including gastrointestinal lesions, abdominal pain, and loose mucoid bloody stool. Furthermore, the colonic muscoa may develop flask-shaped ulcers, and potentially fatal necrotizing colitis. Amebomas, or amebic granulomas, can also occur in rare circumstances and present as white nodular masses, similar to colon carcinomas. Amebomas can become problematic if they

become so large in size that they obstruct the bowel. Toxic megacolon may also occur, typically when the patients also used corticosteroids, and may require surgery. Other life-threatening complications include peritonitis, perforation, shock or in some cases death.

In extreme cases, the parasite is able to leave the colon and can travel through the bloodstream to other locations including the liver, brain, lungs or urinary tract. This even can happen years after initial contact with *E. histolytica* making diagnosis difficult. The most common dissemination occurs via the portal vein, where *E. histolytica* travels to the right lobe of the liver and leads to amebic liver abscesses. ALA presents with symptoms including fever, cough, rigor, chills and dull aching abdominal pain, as well as nausea, vomiting, diarrhea, constipation and abdominal distention, and can be fatal. Anemia and leukocytomia is also common, as is increased levels of alkaline phosphatase and alanine amino-transferase.

There are a number of risk factors that increase this risk of infection with *E. histolytica* and the chance of mortality. Since the parasite is transferred through feces, areas with poor sanitation and unhygienic drinking water are at high risk for *E. histolytica* infection. As with many diseases, malnutrition is linked with *E. histolytica* susceptibility; malnourished individuals are prone to immune deficiency and therefore at risk for *E. histolytica* infection. Living in developed countries does not exempt individuals from amebiasis; travelers and immigrants coming from less industrialized countries may come in contact with *E. histolytica* while away. There is substantial evidence supporting the notion that the composition of the commensal microbiota largely affects the outcome of amebiasis. For example, one study demonstrated that the presence of *Closteridia* species is protective against amebiasis in murine models. Conversely, an increase in *Prevotella copri* has been observed in *E. histolytica* infections, potentially since *P. copri* is associated with inflammation in autoimmune diseases. Certain strains of *E. coli* and *S. dysenteriae* have been found to increase *E. histolytica* virulence, while other *E. coli* strains can actually decrease virulence. Furthermore, it is necessary for commensals to be present for *E. histolytica* to cause a pathogenic disease state. Lastly, there is a link between men having oral-anal or oral-genital sexual contact with other men.

Diagnosis and Recognition

Amebiasis is often suspected when the patient presents with amebiasis-like symptoms and has a history of being exposed to the pathogen. Amebiasis is diagnosed by analyzing stool samples for cysts or trophozoites. It is recommended that a minimum of 3 stool samples be taken during a 10-day period from each patient as *E. histolytica* may appear intermittently. Even with this precaution, it is sometimes impossible to detect *E. histolytica* in the stool of an infected patient. In the case of ulceration, biopsy samples can also be examined to look for the presence of *Entamoeba* species. Intestinal scrapings or aspirates may also be obtained as a sample. Microscopic detection is a standard clinical diagnosis method, however poses a number of challenges. Due to the morphological similarity of *E. histolytica* to non-pathogenic strains *E. dispar* and *E. moshkovskii*, it is almost impossible to microscopically distinguish the species. The exception is when a host erythrocyte is ingested in the ameba; this signifies the presence of *E. histolytica* as the other two species do not phagocytose red blood cells. There is also a risk of mistaking host macrophages or leukocytes for an amebic cyst, leading to a false positive diagnosis. For these reasons, further tests need to be done to confirm the ameba present is in fact *E. histolytica*. A number serological tests such as complement fixation, indirect immunofluorescence assay, the amebic gel diffusion test and immunodiffusion can successfully identify *E. histolytica*, however, they cannot determine if the parasite is currently present or if the patient has been infected in the past. Currently, PCR or ELISA based assays using fecal samples, abscess pus or serum are available to detect *E. histolytica* DNA or antigens and can successfully distinguish between pathogenic *E. histolytica* and non-pathogenic *E. dispar* and *E. moshkovskii*. Since samples are taken at the time of the test, these samples also ensure that the patient is currently infected with the parasite. It is also important to exclude other bacterial and parasitic infections including *Salmonella*, *Shigella*, *E. coli* or *B. coli*, as well as non-infectious causes of dysentery such as inflammatory bowel disease or carcinoma.

Treatment

When determining proper treatment for a patient, it is critical to determine if a pathogenic or non-pathogenic species of *Entamoeba* is present; only *E. histolytica* requires medical treatment. Even if a patient is not presenting with any adverse symptoms, if *E. histolytica* is confirmed it is advised to treat the infection to prevent the parasite from invading the host and causing infection, as well as to prevent the spread of the parasite. Usually in asymptomatic infections, a 7-day course of the amebicidal luminal agent paromomycin is given. In the case of symptomatic amebiasis, nitroimidazoles are prescribed. Numerous nitroimidazoles exist, however, metronidazole is the standard antibiotic given due to its availability in most countries. Although nitroimidazoles, including metronidazole, have unpleasant side effects including diarrhea, nausea, vomiting and abdominal discomfort, it continues to be used as 90% of patients respond to it if followed with luminal agents such as paromomycin or diloxanide to ensure the parasite is removed from the intestinal lumen. Recently, Resveratrol, a plant-based natural phenol, has had success in attenuating *E. histolytica* infection in animal with fewer side effects than nitroimidazoles. This is an exciting development as previous plant-based treatments that were successful in killing *E. histolytica* also killed human cell lines, making them unsuitable for treatment. Another alternative candidate has been found in auranofin, a drug currently used to treat rheumatoid arthritis, as it can decrease *E. histolytica* numbers in various models of amebic colitis and is already approved for use in humans. Furthermore, it has proven to be successful in treating other parasitic infections.

In recent years, metronidazole resistant strains of *E. histolytica* have been created in the laboratory. Although the parasite can survive, multiple important virulence and survival factors are altered. Metronidazole resistant *E. histolytica* show decreased adhesion, a crucial factor in both colonization and invasion for the parasite. Furthermore, the resistant trophozoites are less phagocytic and cytopathogenic, suggesting that they have a severely reduced ability to cause disease. ALA are usually treated the same as intestinal amebiasis; a course of metronidazole followed by either paromomycin or diloxanide. Occasionally, ALA require further treatment than antibiotics. This is the case when antibiotic treatment does not seem to be clearing the infection, or when the patient is at risk of the abscess rupturing due to its size or location. The abscess may be drained either by needle aspiration or catheter drainage; surgical interventions are less likely to be used. Because the abscess may be because coinfecting with bacteria either before or as a result of the drainage, antibiotics may also be prescribed to inhibit a secondary infection. Surgical interventions may be necessary if the infection leads to abdominal or gastrointestinal bleeding, or if toxic megacolon develops.

As with many diseases, the ideal treatment would be a preventative vaccine to eradicate the disease and eliminate need for treatment entirely. To date, no successful vaccine has been identified, but there have been some potential vaccine candidates that have been investigated. Only animal models of vaccination candidates have been tested so far, and although some have had success in protecting against ALA and amebic colitis, no potential vaccine has been able to induce long-term immunological memory against the pathogen. Of these potential vaccines, only 1 has been tested in non-human primates. Although more testing will be needed before it can be tested in humans, a primate study holds promise for a successful candidate against *E. histolytica*.

Virulence Factors

Gal/GalNAc Lectin: Gal/GalNAc lectin is one of the first parasite proteins to encounter host proteins. The Gal/GalNAc lectin protein binds to abundant amounts of galactose and N-acetyl-galactosamine on mucus, allowing the trophozoites to colonize the mucus layer where it can inhabit indefinitely. *E. histolytica* has also been shown to bind to the colonic epithelium, neutrophils and erythrocytes, as well as some types of bacteria. This is a large 260-kDa protein composed of 3 chains; a heavy 170-kDa chain, a light 35 kDa chain, and an intermediate 150 kDa chain. The heavy and light chains are covalently linked via disulfide bonding, whereas the intermediate chain is non-covalently linked to the other 2 subunits. The heavy chain contains a carbohydrate recognition domain (CRD) within a cysteine rich extracellular domain. The heavy chain is also composed of a transmembrane region and a cytoplasmic tail. The light chain is extracellular and contains a glycosylphosphatidylinositol-anchored tail. The light chain has been attributed to amebic virulence; antisense inhibition of the light chain causes less cytopathic and cytotoxic activity, but does not interfere with adhere to target cells. Gal/GalNAc lectin can bind to various host cell receptors and leads to a strong host pro-inflammatory response and the production of various pro-inflammatory cytokines. The heavy chain of Gal/GalNAc lectin is a common antigen targeted by the host's humoral immunity; 90% of patients with a previous *E. histolytica* infection have antibodies against the heavy chain. The Gal/GalNAc lectin adherence to a host cell is a critical prerequisite step for *E. histolytica* to kill host cells. This has been demonstrated by blocking adherence with excess galactose or N-acetyl-galactosamine; when the lectins do not bind to the host cell, there is a decrease in host cell death.

Proteinases: *E. histolytica* has over 50 known cysteine proteinases (CPs), many of which it uses to invade and infect the host while evading host immunity and enhancing survival. These proteins are both secreted and membrane bound. One of the most studied CPs expressed by *E. histolytica* is CP5 as it is present in *E. histolytica* but not in the non-pathogenic *E. dispar*, and has been described in multiple roles of pathogenesis. One of the primary and important roles of CPs is their ability to degrade the protective mucus barrier that overlies the host epithelial layer. The mucus layer is composed primarily of the glycoprotein MUC2, and *Eh*CPs are able to cleave the C-terminal of MUC2 at the IRTT and GKTT sites, destroying the protective barrier and allowing direct access to the epithelial cells. This cleavage is assisted by *E. histolytica* produced glycosidases that can cleave the sugar residues of the MUC2 polymer, exposing it to further degradation by the CPs. Interestingly, *E. histolytica* can also act as a mucus secretagogue. *Eh*CP5 binds to $\alpha\beta3$ integrin on goblet cells and stimulates goblet cells hypersecretion of mucus, which depletes the goblet cell storage of mucus through a protein kinase C (PKC) and Ca^{2+} -dependent pathways. CPs have the ability to cleave both subtypes of IgA in order to avoid antibody recognition and expulsion in the colon, as well as IgG. Purified CPs can also cleave elastin, fibrinogen, collagen and laminin of the extracellular matrix. *E. histolytica* CPs also have a role in complement, an integral part of host humoral immunity. CPs can degrade components of the complement pathway, inhibiting the cytotoxic and pro-inflammatory effects of the complement pathway. Although many of the roles of *Eh*CPs revolve around immune evasion and host invasion, it has also been suggested that CPs play an important role in nutrient acquisition and proper encystation. E-64 (*L-trans*-epoxysuccinyl-leucylamido(4-guanidino) butane) from the fungi *Aspergillus japonicus* has been shown to be a broad cysteine proteinase inhibitor, and indeed E-64 does inhibit the proteinase activity of *E. histolytica* and therefore prevents the destruction of host epithelial cells. Antisense inhibition of CP5 greatly reduces the parasites ability to degrade mucus, and also prevents the formation of liver abscesses, demonstrating the importance of CP5 for *E. histolytica*.

Amoebapore: Another virulence factor *E. histolytica* uses to infect and invade host cells is its use of a pore-forming peptide termed the amoebapore. Like other pore-forming toxin, the amoebapore kills host cells by forming a transmembrane pore in the host cell wall. The amoebapore is a 5kDa protein made of 77 amino acids including 6 cysteines that forms a α -helical structure held together by disulfide bonds. The amoebapores are stored in granules in the cytoplasm of *E. histolytica* until released. Granules also contain lysozyme, phospholipase A2, calcium-binding protein and cysteine proteinase. To date, 3 pore-forming proteins have been identified and are entitled amoebapore A, B and C, with the latter being the most potent. The amoebapore functions optimally

in acidic conditions of approximately pH of 5.2, and has no activity above pH 6. The virulent peptide is able to kill eukaryotic cells as well as both gram positive and gram-negative bacteria. Once in contact with a human host cell, the host cell swells and loses its membrane integrity, consistent with necrosis, which then leads to inflammation due to an influx of leukocytes. The proposed mechanism of action for the amoebapore is the barrel-stave mechanism. Briefly, the amoebapore polypeptides form helices and insert into the cell membrane of the target cell, forming a channel that allows the cytoplasmic contents of the target cell to pass through, resulting in a drastic change of cytoplasmic content and eventually cell lysis and death. Hydrophobic regions of the helices interact with the phospholipids of the membrane, and the hydrophilic regions create the inner side of the channel where water, ions and other cytosolic components pass through. Interestingly, amoebae are immune from their own amoebapores as the peptide is unable to bind to the lipid membrane of *E. histolytica* and therefore the amoebapore cannot insert and damage the parasite itself. Removing the amoebapore through either transcriptional silencing or antisense inhibition drastically affects the pathogenicity of *E. histolytica* and removes the ability of the parasite to form liver abscesses.

Apoptosis and Phagocytosis: As previously mentioned, Gal/GalNAc adherence to the target cell is a necessity for killing host cells. In addition to Gal/GalNAc *E. histolytica* has a STIRP (serine, threonine and isoleucine rich protein) protein and surface LPPG (lipophosphopeptidoglycan), both of which are associated with adherence and cell cytotoxicity. Adherence to a target host cell induces the first step in amebic caused apoptosis: an increase in calcium. Up to a 20-fold increase in host cell calcium has been reported. As the calcium increases intracellularly, the host cell becomes dephosphorylated. This dephosphorylation starts with calcium activating the protein calpain, a calcium dependent protease. Once active, calpain proteolytically cleaves PTP1b, a PTPase that is known to cause cell dephosphorylation. Both of these events appear to be mandatory; blocking calcium influx or the dephosphorylation inhibits *E. histolytica* killing of the host cell. These events lead to a change in the host cell morphology including chromatin condensation, blebbing and DNA fragmentation. This inevitably leads to caspase-3 dependent apoptosis. There have also been observed host cells dying in a fashion more consistent with necrosis following contact with *E. histolytica*, so it is important to note that cytotoxicity may not be strictly an apoptotic response. Host cell death is observed within minutes.

After apoptosis, *E. histolytica* phagocytoses the cells. This is beneficial as it removes dead cell components that could alert host immune cells of a problem from the area, avoiding detection and inflammation. This can also explain how *E. histolytica* can cause high degrees of tissue damage without causing inflammation. Interestingly, apoptosis appears to be a pre-requisite for phagocytic uptake in *E. histolytica*; healthy cells nor necrotic cells are not phagocytosed by the parasite, but apoptotic cells readily are engulfed. Phosphatidylserine is exposed on apoptotic cells and is used by *E. histolytica* to recognize apoptotic cells. There is also evidence of *E. histolytica* trans-membrane kinases (TMK) and serine rich *Eh* protein (SREHP) facilitating phagocytosis in addition to phosphatidylserine. Additionally, F-actin and myosin 1B are necessary to form a phagocytic cup and ingest the apoptotic host cell. Phagocytosis-deficient *E. histolytica* are less virulent and cannot cause liver abscesses. The avirulent *E. dispar* does not phagocytose host cells. Accordingly, the presence of visible phagocytosed erythrocytes is used to differentiate *E. histolytica* from *E. dispar*.

Trogocytosis: A unique method *E. histolytica* uses to kill host cells is amebic trogocytosis, a form of cell killing based off the Greek word "to nibble". Within as little as 1 minute of contact with a human host cell through the Gal/GalNAc, *E. histolytica* has been shown to internalize small fragments of the host cell's membrane, which eventually leads to cell death due to an increase in intracellular calcium and eventually the loss of membrane integrity. The phenomenon of trogocytosis only occurs with live host cells; once the cell dies, the ameba detaches from the host cell and trogocytosis ceases. Similarly, when *E. histolytica* comes in contact with host cells that are already dead, trogocytosis does not occur. Instead, the parasite ingests pre-killed cells via phagocytosis. Killing host cells through trogocytosis, especially epithelial cells, may be another method *E. histolytica* uses to invade the epithelium. Trogocytosis occurs at physiological pH, and requires actin polymerization at the site of host cell contact, as well as *E. histolytica* C2-domain-containing protein kinase (EhC2PK) and phosphoinositide-3-kinase (PI3K) signaling.

Alteration of Host Tight Junctions: Removing the mucus layer allows direct contact with the host epithelial cells, but does not allow access to the basolateral side, as epithelial cells are tightly bound together creating tight junctions. This protective barrier is designed to keep unwanted pathogens and toxins out of the basolateral surface. The families of proteins claudins (CLDN) and occludins (OCLN) are transmembrane proteins that create the backbone of the barrier between neighboring cells. These proteins bind with intracellular proteins such as zona occludins (ZO) to anchor and stabilize the tight junction structure. When the tight junction complex is altered, pathogens and their secreted products can invade the underlying basolateral surface and cause further disease and damage. *E. histolytica* has a number of ways to overcome this host mechanism and further its invasiveness.

When in contact with the epithelial cells, *E. histolytica* proteases have been shown to remove portions of the tight junction structure leading to an increase in paracellular permeability and a decrease in TER. Live *E. histolytica* contact with epithelial cells lead to ZO-1 and ZO-2 releasing from each other, ZO-2 dephosphorylation, and decreased presence of ZO-1, leading to decreased integrity of the tight junction complex. *E. histolytica* also induces a very strong pro-inflammatory response through activation of the transcriptional regulator NF- κ B. Multiple cytokines are upregulated including IL-1 β , IFN- γ , TNF- α . Intriguingly, upregulation of these pro-inflammatory cytokines has been shown to alter the tight junction proteins leading to increased paracellular permeability. Therefore, *E. histolytica* can disrupt the tight junctions of host epithelial cells directly by proteinases interacting with tight junction proteins, or indirectly by inducing the host immune system to up regulate tight junction-altering cytokines. *E. histolytica* also has an occludin-like protein that can disrupt tight junction barrier integrity possibly by displacing and replacing the host occludin protein.

Another method is based on the inflammatory molecule prostaglandin E₂ (PGE₂), a prostanoid found throughout the GI tract that regulates physiological functions such as mucosal protection, intestinal secretions including increased mucus secretions, vasodilation and peristaltic movement. An increase in PGE₂ has been shown in inflammatory disease such as colitis, Crohn's disease and intestinal inflammation. *E. histolytica* has been shown to stimulate host macrophages to up regulate PGE₂. Furthermore,

the parasite can synthesize and secrete PGE₂. PGE₂ is formed when arachidonic acid, a fatty acid found commonly in the gastrointestinal tract, is transformed to prostaglandins by cyclooxygenase (COX) enzyme. Interestingly, *E. histolytica* has a COX-like enzyme, and is therefore able to synthesize and secrete PGE₂, and can disrupt tight junctions by altering claudin-4 and induce an inflammatory response through PGE₂ binding to host E-prostanoid-4 (EP4) receptors. PGE₂ also creates a NaCl gradient that may cause water flow and eventually diarrhea, a frequent event in intestinal diseases that can also increase the spread of infection. *E. histolytica* can also alter the tight junctions through its EhCPADH112 complex. Composed of the cysteine proteinase EhCP112 and an adhesin EhADH112, this virulent complex can bind to tight junction components including occludin, claudin-1 and ZO-1 and ZO-2. Once bound to the complex, these proteins are targeted for proteasome degradation or dissociation, resulting in a decrease in tight junction function.

Host Immune Evasion

Innate Host Immunity: The human body is filled with complex innate immune strategies that are constantly present and ready to defend against any potential pathogens (Table 2). When *E. histolytica* is initially ingested as an infectious cyst, it enters the stomach, which is rich in acidic secretions meant to destroy pathogens. However, the cyst's chitinous cell wall is resistant to acid in the stomach, and therefore is able to pass through and enter the intestine. The human mucus layer, composed primarily of MUC2, is the next major innate defense against *Eh*. The mucus layer is designed to keep the microbiota and potential pathogens away from intestinal epithelial cells, however, *E. histolytica* can easily overcome this barrier using its cysteine proteinases to cleave the MUC2 monomers, destroying the mucus layer and allowing contact with the epithelial cells and inducing the expression of antimicrobial peptides. Human β -defensin 2 and cathelicidins are some of the main antimicrobial peptides released upon contact with *E. histolytica*, but the parasite has been shown to be less susceptible to both defensin and cathelicidin killing, overcoming yet another innate defense.

Pro-inflammatory response: Since *E. histolytica* is able to overcome various innate immunity strategies employed by the host, further immune responses are perpetuated in order to clear infection. When an epithelial cell comes in contact with *E. histolytica* through its Gal/GalNAc lectin, the host cells elicits a potent pro-inflammatory response including a variety of cytokines to alert immune cells and recruit them to the site of infection, including interleukin-1 (IL-1 β), IL-8 and tumor necrosis factor- α (TNF- α) through NF- κ B. Similarly, CP5 can bind α V β 3 integrin via the RDG motif on colonic epithelial cells, stimulating a pro-inflammatory response through NF- κ B.

Neutrophils: The first immune cells to respond to an *E. histolytica* infection are neutrophils. These host cells try to remove the parasite from the area by releasing reactive oxygen species (ROS). The parasite is not harmed by the oxidative stress as it contains a number of mechanisms to overcome neutrophil attack. It can inhibit the release of ROS from neutrophils all together, or it can use its superoxide dismutase and NADPH:Flavin oxidoreductase enzymes to turn ROS species into H₂O₂. The parasite then detoxifies H₂O₂ with a surface protein, peroxiredoxin, a potent antioxidant and can degrade H₂O₂, rendering it undamaging. *E. histolytica* also secretes EhSERP, a serine protease inhibitor that binds and inactivates the neutrophil serine protease cathepsin G, rendering it useless. Furthermore, a single *E. histolytica* trophozoite can kill as many as 3000 neutrophils through inducing NADPH oxidase and ROS-mediated apoptosis. Not only does the neutrophil death help *E. histolytica* spread and survive, but it also contributes to the extensive tissue destruction associated with amebiasis. As neutrophils die, their intracellular contents such as lysozymes, hydrolases and proteases are released and can damage the nearby intestinal epithelial cells. As intestinal cells are damaged, they release

Table 2 Host immunity against *E. histolytica*

Immune component	Function
Mucus layer	Prevents pathogens from reaching underlying epithelial cells
Neutrophil	release ROS to kill pathogens contains serine protease cathepsin G that degrades pathogens contain various lysozymes, hydrolases and proteases
Macrophage	PRRs detect pathogens release NO produce a pro-inflammatory response to stimulate apoptosis, cell proliferation and attract other cells activate inflammasome response to secrete pro-inflammatory cytokines
Complement	cascade leads to the formation of the membrane attack complex which lyses pathogens components of the complement pathway are potent anaphylatoxins
Immunoglobulins	produce memory antibodies against pathogens neutralize pathogen surface molecules activate complement
Tight junctions	prevents pathogens from reaching the basolateral surface of the epithelial cells
Stomach acid	low pH kills many pathogens as they enter the stomach

pro-IL-1 β , which CPs can convert into active IL-1 β . Conversely, neutrophils activated by both IFN- γ and TNF- α are successful in killing 67% of *E. histolytica* trophozoites in 6 h. Interestingly, PGE₂ from *E. histolytica* can induce the neutrophil chemokine IL-8.

Macrophages: Another type of immune cell that is quick to infiltrate an amebic infection is macrophages. They are recruited by monocyte chemotactic protein (MCP) from intestinal epithelial cells that have come in contact with *E. histolytica* soluble proteins. Gal/GalNAc recognition by PRRs TLR-2 and TLR-4 can stimulate naïve macrophages to produce the pro-inflammatory cytokine TNF- α which can not only upregulate other pro-inflammatory cytokines but can also induce apoptosis, stimulate cell proliferation and act as a chemoattractant. This pro-inflammatory response can assist macrophages in killing trophozoites, or it can limit the growth of the parasite. Macrophages can also be activated by IFN- γ ; higher levels of IFN- γ correlate with lower frequency of *E. histolytica* infecting a host and appear to have a protective role in amebic infection. Macrophages release NO in order to harm parasites, and can effectively kill *E. histolytica* trophozoites by inhibiting cysteine proteinases and alcohol dehydrogenase. However, *E. histolytica* has developed multiple strategies to evade the macrophage immune response. The *E. histolytica* arginase enzyme limits the amount of NO produced by converting L-arginine, the substrate for NO, into L-ornithine, stopping the production of NO. The parasite also produces monocyte locomotion inhibitory factor (MLIF) that inhibits NO production. In addition to MLIF, *E. histolytica* also produces macrophage migration inhibitory factor (MIF), which can increase macrophage TNF- α secretion, leading to a more pronounced pro-inflammatory response, furthering tissue damage. *E. histolytica* can synthesize PGE₂, which can inhibit Th1 cytokine release as well as oxidative bursts and NO synthesis. PGE₂ can also inhibit class II MHC genes, blocking the antigen presenting capabilities of macrophages. An interesting interaction between *E. histolytica* and host macrophages is the activation of the NLRP3 inflammasome in macrophages. When live *E. histolytica* binds to a macrophage via the Gal/GalNAc lectin, the inflammasome becomes activated and secretes pro-inflammatory IL-1 β and IL-18. This cytokine response is beneficial for the host as it can enhance the pro-inflammatory response against the parasite, but it can also be detrimental as it can lead to further tissue damage. Macrophages must be stimulated with IFN- γ , TNF- α and macrophage colony-stimulating factor-1 in order to mount a successful response against *E. histolytica*.

Eosinophils: Recently, a role for eosinophils has been discovered. IL-25 from eosinophils is down regulated in cases of amebic colitis, however replenishing IL-25 can reduce the severity of *E. histolytica* infection and protect the intestinal epithelial cells by suppressing pro-inflammatory cytokines, including TNF- α , which has been shown to have a harmful effect in *E. histolytica* infection. Furthermore, induction of eosinophils may reduce the severity and size of ALA.

Complement Cascade: Complement is another immune strategy employed by the host in case of *E. histolytica* infection. When activated successfully, complement creates the membrane attack complex (MAC) that can lyse invading pathogens, including *E. histolytica*. The Gal/GalNAc lectin of *E. histolytica* antigenically resembles host CD59, a MAC-inhibitory protein, and therefore inhibits and avoids MAC-activated lysis. The parasite cysteine proteinases can activate the alternative complement pathway by cleaving the α -chain of C3. Furthermore, *Eh*CPs cleave complement anaphylatoxins C3a and C5a, inhibiting the complement pathway and stopping the toxins from causing mast cell histamine release, macrophage IL-1 β release, chemotaxis of neutrophils and increase vascular permeability. Lastly, *E. histolytica* Gal/GalNAc lectin can bind complement components C8 and C9, blocking them from forming the MAC.

Humoral Immune Response: *E. histolytica* induces a strong humoral immune response. Over 80% of amebiasis patients develop circulatory antibodies within the first week of infection. The Gal/GalNAc lectin is immunogenic; plasma cells in the lamina propria produce mucosal IgA against this portion of *E. histolytica*. The presence of sIgA correlates with a decrease in future *E. histolytica* infections. Anti-ameba IgG is also produced during amebic invasion; however, it correlates with more frequent and more severe future infections. Regardless of the consequence of the immunoglobulin, cysteine proteinases cleave both sIgA and circulatory IgG. *E. histolytica* has also been shown to utilize an immune evasion strategy known as receptor capping, a method where the parasite redistributes surface receptors that have been recognized by host immune cells. Recognized surface-bound molecules are translocate to the posterior end of the cells where they are cluster to form a cap and are then released as membrane bound vesicles, eliminating the host immune system's ability to recognize the parasite. The serine proteinase rhomboid protease (ROM1) is partially responsible for the translocation and release of antigenic materials. Interestingly, ROM1 has been shown to cleave the Gal/GalNAc lectin, a protein that is often recognized by host immune cells. It is suggested that ROM1 may continually cleave Gal/GalNAc lectin from the surface of the parasite, hindering the immune system from targeting the parasite.

Immune Evasion: Since 90% of *E. histolytica* infections are asymptomatic, there must be some methods by which the parasite can avoid the potent pro-inflammatory and invasive response. Soluble amebic proteins (SAPs) have been found to suppress NF- κ B signaling; thereby inhibiting NF- κ B mediated inflammation. SAPs unregulated heat shock proteins 27 and 72 (Hsp27 and Hsp72), associated with stress response and protective effects. Hsp27 and Hsp72 have been shown to inhibit NF- κ B signaling in response to SAPs, lessening the pro-inflammatory and apoptotic events, alleviating epithelial damage. This could explain why the vast majority of people carrying *E. histolytica* do not display symptoms; however, it is unknown why or how the parasite turns from harmless to invasive.

Concluding Remarks

Dating back for centuries, *E. histolytica* has become a well characterized human pathogen. In most circumstances, *E. histolytica* lives as a harmless member of the hosts microbiota. However, in a small portion of the population, the organism invades tissues causing a range of symptoms causing disease both in and outside of the intestinal tract including diarrhea, fever, intestinal ulcers and liver

abscesses. Although diagnostic technologies have improved with advances in science, the similarities of pathogenic *E. histolytica* with non-pathogenic *E. dispar* and *E. moshkovskii* can make diagnosis challenging. Furthermore, although largely successful, the current effective treatment options often are accompanied with a variety of unpleasant side effects. The success of *E. histolytica* as a pathogen is due to its numerous virulence factors such as Gal/GalNAc lectin, cysteine proteinases and the amoebapore. Although the host is able to create a robust immune response in the presence of infectious *E. histolytica*, the parasite has a number of ways to evade and overcome host immunity, and often the host immune response is responsible for some of the intestinal damage associated with *E. histolytica* infection. Clearly, more studies are needed to understand how to prevent *E. histolytica* infection globally with vaccines and how to treat infection without creating more symptoms and host damage.

Enteric Viruses[☆]

Christiane E Wobus and Sophia A Svoboda, University of Michigan, Ann Arbor, MI, United States

Infectious gastroenteritis or diarrhea remains a significant health burden worldwide. Although global diarrheal deaths have declined in recent years, morbidity remains unchanged. Many pathogens, including viruses, bacteria and parasites, can cause diarrhea. These pathogens target the gastrointestinal tract for replication. Transmission to new hosts occurs via the fecal-oral route, when the pathogens are ingested via contaminated food or water or fomites, and are shed in the feces following replication. Thus, the pathogens that infect via the intestine have evolved numerous strategies to overcome host barriers at the intestinal surface to establish a successful infection. Most viruses that infect the intestine are non-enveloped. This allows these viruses to survive in the harsh environment of the stomach *en route* to the intestine. It also makes these enteric viruses relatively resistant in the environment and to disinfection, making processes like water treatment more difficult. Enteric viruses are shed from days to weeks in very large quantities (up to 10^{11} viruses/g stool), and they are infectious at low doses, promoting their spread. Many different viruses cause food- and waterborne infections. These include viruses with DNA genomes (e.g., adenovirus serotypes 40 and 41, bocavirus, and Torque teno virus), viruses with positive-sense, single-stranded RNA genomes (e.g., norovirus, sapovirus, astrovirus, aichivirus, the picornaviruses, cosavirus, salivirus, enterovirus, hepatitis A virus, and hepatitis E virus), and viruses with double-stranded RNA genomes (rotaviruses). While many of these infections are asymptomatic or mild and not diagnosed, others lead to morbidity and mortality. Given their prevalence, the focus of this review will be on noroviruses, sapoviruses, rotaviruses, adenoviruses and astroviruses.

Caliciviridae

The name “Caliciviridae” is derived from the ancient Greek word *calyx*, meaning “cup” or “goblet”, because of the chalice-like structures of the viral capsid that can also appear as six-pointed stars in electron micrographs. Their icosahedral capsids are ~32 nm in diameter, non-enveloped and encapsidate a non-segmented, positive-sense, single-stranded RNA genome. Viruses in this family infect a range of vertebrate animals, including dogs, cats, dolphins, rabbits, mice, pigs, cows and humans. They are classified into genera, subdivided into genogroups, and further separated into genotypes based on phylogenetic analysis. Currently, five genera are officially recognized: Vesivirus, Nebovirus, Lagovirus, Norovirus, and Sapovirus. These viruses cause a wide range of symptoms. Vesiviruses, like feline calicivirus (FCV), cause respiratory disease among cats; neboviruses, like the Newbury-1 virus, cause gastrointestinal disease in cows; and lagoviruses, like rabbit hemorrhagic disease virus (RHDV), cause hepatitis in rabbits; while noroviruses and sapoviruses cause sporadic and epidemic outbreaks of gastroenteritis in humans and thus will be discussed below in more detail.

History and Epidemiology

The first norovirus, Norwalk virus, was visualized by electron microscopy in the stool of an elementary school student from Norwalk, OH, in 1972. A few years later in 1977, the first sapovirus, Sapporo virus, was discovered in a stool sample from a child in Sapporo, Japan. Noroviruses and sapoviruses cause primarily vomiting and/or diarrhea. While either disease is rarely lethal, norovirus infects all age groups and more severe disease is observed in the very young, the elderly and immunocompromised individuals. The incubation period for norovirus is between 24 and 48 hours, the duration of illness for otherwise healthy adults is 1–3 days, and the mean duration of shedding is 10 days. Compared to noroviruses, sapovirus infections occur more often in children and typically result in less severe disease. Of all enteric viruses, noroviruses are the most prevalent and responsible for almost one fifth (18%) or 685 million cases of acute gastroenteritis worldwide with an estimated price tag of about \$60 billion per year. Approximately 200,000 children under the age of 5 die every year in developing countries from norovirus infections. Asymptomatic infections are common and approximately 7% of healthy individuals worldwide unknowingly shed virus. Norovirus is spread most commonly via person-to-person contact but also by contaminated food and water, or in vomitus. Thus, outbreaks occur most often where large populations interact in close quarters, such as schools, military bases, cruise ships, and nursing homes, but frequent transmission also occurs in restaurants or via catered meals. Outbreaks occur all year long and propagate easily due to the low infectious dose of noroviruses (estimated to be as low as 18 particles). Furthermore, norovirus particles are highly stable in the environment, e.g., particles remain infectious in ground water for several months and are resistant to standard concentrations of chlorine in drinking water.

Noroviruses are highly genetically diverse. While genogroup I (GI) strains are more often transmitted via water, most outbreaks are caused by genogroup II (GII) viruses, in particular the genogroup II genotype 4 (GII.4) viruses. This cluster is unique as it is undergoing continuous genetic and antigenic drift resulting in new antigenic variants that can cause global epidemics. Other GI and

[☆]Change History: Christiane Wobus, March 2018. Changes made to all text.

GII genomes have differed only slightly over several decades, they remain “static”. The genetic diversity of noroviruses is further increased by frequent mixed infections resulting in recombination between strains.

Structure

The norovirus genome is approximately 7.5 kb long and consists of three or four open reading frames (ORFs). Sapovirus genomes are of similar length and encode two or three ORFs. The 5′ end of the norovirus genome is linked to a viral protein (VPg), while the genomic 3′ end of both viruses has a poly(A) tail. The capsid structure of sapovirus is more similar to animal caliciviruses in the Vesivirus genus than to norovirus.

The norovirus ORF-1 encodes a large polyprotein that is cleaved by the viral protease into 7 non-structural proteins, which are required to replicate the viral genome, including the protease and RNA-dependent RNA polymerase. ORF-2 and ORF-3 encode the major capsid protein VP1 and minor capsid protein VP2, respectively. 180 copies of VP1 form the viral capsid, while a few copies of VP2 are located inside the capsid to facilitate stability and genome packaging. VP1 is divided into two domains. The S domain on VP1 is highly conserved and forms the shell (S) around the genome. It is used by the virion as a scaffolding for the P domain (protruding domain), which contains the receptor binding and antigenic sites and is more variable. The neutralizing antibody response is mainly directed against the P domain.

Binding and Replication

Human noroviruses have remained refractory to cell culture for over 40 years. Currently, two cell culture systems have been described that enable replication of some isolates in either primary human intestinal epithelial organoid cultures or the human B cell line BJAB. However, human sapoviruses remain unculturable to date. Knowledge about the cellular life cycle of these viruses thus comes largely from the related murine norovirus and porcine sapovirus, which can be cultured. Following attachment of murine norovirus to carbohydrates on the cell surface, the virus binds its proteinaceous receptor CD300lf, which also binds ceramide on the cell surface. Expression of the proteinaceous receptor is required for infection and determines host cell tropism. Following receptor binding, norovirus virus particles enter the cell via endocytosis. Porcine sapovirus binds to cell surface glycans and requires bile acids for infectivity *in vitro* but proteinaceous receptor(s) and entry mechanisms remain unknown. Like all positive-strand RNA viruses, once the genome has reached the cytosol, it functions as mRNA in protein translation. The 5′-linked VPg recruits the cellular translation apparatus. After translation of the ORF-1 polyprotein, it is cleaved by the viral protease to release the non-structural proteins, which recruit intracellular membranes and form the replication complex. Genome replication is performed by the viral polymerase, which generates genomic and subgenomic length RNAs via a negative-sense intermediate. The subgenomic RNA is translated to make capsid proteins, which then encapsidate the viral genome. Packaged virions are released from the cell by lytic and non-lytic mechanisms.

Pathogenesis

Noroviruses and sapoviruses cause species-specific infections. Thus, information on viral pathogenesis comes from a combination of epidemiological studies, human volunteer studies, and studies in animal models. Typically, these animal models either investigate mechanisms of human viruses in non-human hosts or related, non-human viruses (also referred to as “surrogate” viruses) in their native hosts. Each of these models has strengths and limitations but none of these models recapitulates all aspects of human noro- or sapovirus infections.

Noroviruses and sapoviruses cause villus blunting and atrophy in the small intestine. While the cell types infected by human sapovirus *in vivo* remain unknown, porcine sapovirus antigen has been detected in villous enterocytes in the proximal small intestine. Human, murine and bovine noroviruses were shown to replicate in epithelial and immune cells in the small intestine. More specifically, human and murine noroviruses replicate in macrophages, dendritic cells, B and T cells, in addition to intestinal epithelial cells. Extraintestinal spread of noroviruses can also occur with some strains. The cause of norovirus diarrhea is still under investigation but one study suggested epithelial barrier and secretory pathway dysfunction. This dysfunction may be due to a cytokine storm as another study demonstrated increased serum cytokine levels in symptomatic versus asymptomatic patients despite similar viral loads. On the other hand, nausea and vomiting may be caused by abnormal gastric motor function and delayed gastric emptying, which has been observed in some human volunteers.

Immunity to human noroviruses is poorly understood and resistance to infection is both genetic and immunologic. Histo-blood group antigens (HBGAs) are a genetic susceptibility factor for human noroviruses. Human noroviruses bind to these carbohydrates, which are present on intestinal epithelial surfaces, red blood cells, and in saliva. Related structures are also found on intestinal bacteria and even plant leaves. These molecules are thought to serve as attachment factors on the host cell surface, but the precise function during pathogenesis remains unclear. No susceptibility factor has been identified for human sapoviruses to date. While human sapoviruses have not been shown to bind HBGAs, other cell attachment factors like sialic acid might be used by both virus families. Noroviruses and sapoviruses are sensitive to interferons, and innate immune responses are required to control levels of norovirus titers *in vivo*. Furthermore, adaptive and cellular immune responses develop following norovirus infection. However, immunity to noroviruses is short-lived and volunteer studies indicate that people can be reinfected by the same strain after only one year. In mice, antibody and CD4 and CD8 T cell responses are required for murine norovirus clearance.

from immune cells, while interferon lambda clears infection from specialized intestinal epithelial cells called tuft cells during persistent infection.

Vaccination and Treatment

No specific vaccine or antiviral is approved for use against norovirus or sapovirus infections. Supportive treatment, rest and rehydration for the infected individual are currently used for standard care. Strategies to limit spread, such as enhanced hygiene, disinfection, and isolation techniques, are imperative, for example, in hospitals, food service establishments, and schools to reduce outbreaks.

Virus-like particles and the P domain subunit are under development for a norovirus vaccine. However, biological and logistical/programmatic challenges need to be overcome in the future to have a global impact on disease burden. For example, noroviruses are highly antigenically and genetically diverse and major gaps exist in our knowledge about anti-norovirus immunity, presenting a challenge for generating broadly protective immune responses. At the same time, approaches for both virus-targeted and host-based antivirals are being investigated, which ultimately may complement the arsenal available to combat these highly prevalent viruses.

Astroviridae

Astroviruses resemble stars when viewed by electron microscopy, so these viruses were given the name “Astrovirus” from “astron” meaning “star” in Greek. Like caliciviruses, astroviruses have icosahedral, non-enveloped capsids of ~32 nm containing a positive-sense, single-stranded RNA genome. They infect vertebrates and typically cause gastroenteritis in the young, including humans, pigs and birds, but fatal hepatitis and growth-stunting nephritis have also been observed in birds. Several new astroviruses have been isolated recently, increasing genetic diversity within this virus family. Based on the capsid sequences, astroviruses are classified into two genera *Mamastrovirus* and *Avastrovirus*, which are currently further subdivided into 19 and 3 genotypes, respectively. Astroviruses infecting humans are found in 3 clades: classical human astrovirus (HAsV), MLB-like and VA-like. Although astroviruses were thought to cause species-specific infections, recent phylogenetic evidence suggests that cross-species infection events have occurred.

History and Epidemiology

Human Astrovirus (HAsV) was first observed in 1975 using electron microscopy in the stool of children with acute gastroenteritis. In the same year, astrovirus was also found in hospitalized infants suffering from acute gastroenteritis. In 1981, HAsV was first grown and passaged in cell culture, leading to the characterization of 8 different serotypes for classical HAsV. Typical HAsV infections are mild or asymptomatic, and disease is found in children, the elderly, and the immunocompromised. The incubation period is approximately 4.5 days long before the onset of watery diarrhea, which lasts 1–4 days and is sometimes accompanied by vomiting, fever, and abdominal pain. Symptoms usually resolve spontaneously but in immunocompromised patients the virus can spread systemically, and on rare occasions can be fatal. Infections occur worldwide, are very common, and most children are found to be seropositive but their immunity wanes over time. The classical HAsVs cause ~2%–9% of acute gastroenteritis cases in children worldwide but studies including the recently identified MLB- and VA-like astroviruses are urgently needed to assess the full prevalence of these viruses. Infections predominantly occur in the winter months or during the rainy season and are common in locations where crowds gather. Food, water and fomites are transmission vehicles, hence the exacerbation of outbreaks can be due to poor hygiene practices.

Structure

Astroviruses encapsidate their non-segmented, ~7 kb RNA genome into non-enveloped particles of icosahedral symmetry. Their genome has a viral protein (VPg) linked to the 5′ end and a 3′ poly(A) tail. It encodes three ORFs: ORF1a, ORF1b, and ORF2. ORF1a and ORF1b encode two nonstructural polyproteins, which are further proteolytically processed and are responsible for transcription and replication. ORF2 encodes the capsid protein VP90. The protein is divided into 3 domains: the conserved N-terminus, a hypervariable domain, and a genetically variable C-terminus. Capsid assembly first yields an immature capsid following cleavage of the capsid protein VP90 to the VP70 form. Further proteolytic cleavages then result in a fully mature capsid with the C terminal domain (VP27 and VP25) forming the spikes on the virion surface and the N-terminus (VP34) forming the core surrounding the genome.

Binding and Replication

Astrovirus replication is poorly understood. The identity of any cellular receptors for these viruses is unknown. Treatment with trypsin has been found to enhance the virus’ infectivity 3- to 5-fold by cleaving the viral polyproteins resulting in dramatic structural changes. Treatment with dextran sulfate, heparin sulfate, and heparin prevented infection of cells with HuAsV while treatment with sialic acid has no effect suggesting that a carbohydrate molecule acts as a receptor for the virus, similarly to caliciviruses. Binding of the virus to differentiated intestinal epithelial cells results in changes in tight junction proteins and

increased barrier permeability. The replication cycle for astroviruses is similar to that of viruses from the *Caliciviridae* family. The virus is endocytosed into cells, the genome is released into the cytoplasm and the two nonstructural polyproteins are translated from the incoming genomic RNA. The proteins then form viral replication complexes that associate with intracellular membranes and replicate the genome. New virions are formed and mature until their release from the cell in a largely non-lytic manner.

Pathogenesis

Little is known about astrovirus pathogenesis. These viruses are thought to infect mainly intestinal epithelial cells in the small intestine, but some mamastroviruses have also been observed to infect sub-epithelial macrophages and M cells of the small intestine. How astroviruses cause disease is still under investigation. In general, infections are not associated with an inflammatory response or cell death in the intestine.

Turkey astrovirus-2 (TAstV-2) in young turkeys is the most common animal model to study astrovirus pathogenesis. Turkeys suffer from diarrhea within 1–3 days of infection and symptoms persist for an additional four days. After infection, virus can be found in the blood and many other tissues of young turkeys, indicating viremia. However, the gut is the only place where replication occurs. Infection causes only mild histopathologic changes and is not associated with inflammation in the intestine. One study demonstrated that oral administration of the TAstV-2 capsid protein caused diarrhea in turkeys by increasing intestinal epithelial barrier permeability and internalization of the sodium hydrogen exchanger 3. Based on these data, the astrovirus capsid is thought to function as an enterotoxin. More recently, murine astrovirus was discovered in biomedical mouse research colonies. No obvious symptoms are observed in mice, likely resulting in the endemic spread of this virus. In the mouse model, both innate and adaptive immune responses are required to clear the infection and type I interferons protect from virus-induced barrier permeability.

Vaccine and Treatment

No specific antiviral treatments or vaccines are available. Supportive treatment is used for those who require hospitalization. HuAstV spread is best controlled by limiting its transmission. Hygienic practices like disinfection of fomites, cleaning and cooking of food, and decontamination of drinking water can prevent the virus from causing an outbreak. However, little information is available regarding effective decontamination procedures. Limited studies indicate that different strains exhibit different levels of resistance to environmental decontamination by chlorine and alcohol.

Rotavirus (Reoviridae)

Rotavirus was named after the Latin word “rota”, meaning “wheel” because the structure is such that the particle appears to have spokes and a smooth rim. Rotaviruses (RV) are a genus in the *Reoviridae* family, which cause significant morbidity and mortality worldwide. They are the second largest cause of non-bacterial acute gastroenteritis in the world in all age groups, behind noroviruses. In children, rotaviruses are the leading cause of life-threatening diarrhea. In addition, 14 other genera are classified within the *Reoviridae* family. Members of the *Orthoreovirus* genus can also infect humans via the intestine but infections are rarely symptomatic. When the virus does cause symptoms, they can include a cough, pharyngitis and gastroenteritis. Orthoreovirus infections can also be associated with neonatal biliary atresia which entails inflammation of intrahepatic bile ducts, infection of the central nervous system, myocarditis, and pneumonia.

History and Epidemiology

Rotavirus (RV) was first discovered in the 1970s alongside norovirus. In 1973, viral particles were visualized by electron microscopy in feces. Although this was the first rotavirus infection recorded in humans, it was later discovered that gastroenteritis infections in other mammals in years previous had also been due to rotavirus. To date, at least eight rotavirus species, *Rotavirus A* (RVA) to *Rotavirus H* (RVH), have been classified. These viruses are further classified into genotypes based on nucleotide sequences of the VP7 (G) and VP4 (P) capsid genes. Most recently, the classification is being expanded to contain sequence information of the other nine proteins. Most cases of rotavirus gastroenteritis are caused by 5 genotypes but regional and temporal differences in the distribution of genotypes have been noted. However, new strains evolve continuously due to point mutations by the viral RNA-dependent RNA polymerase and reassortment of the gene segments during co-infections. Although largely species-specific, zoonotic transmission events have been detected, particularly for RVA, which infects birds and mammals.

Symptomatic RV infections mostly occur in children <5 years of age, at which point almost all children have been infected. Prior to universal vaccination, half a million children died from excessive fluid loss due to RV gastroenteritis each year, mostly in developing countries. All age groups can become infected, but mild or asymptomatic infections are typically seen in older children and adults. While infections can occur throughout the year, most cases show seasonality during the winter months or the dry season. The incubation period is ~2 days and symptoms last 3–5 days. Spread occurs via person-to-person contact and often occurs in settings with small children, e.g., daycares, schools, and households.

Structure

The icosahedral particles are approximately 100 nm in diameter, which is large for a non-enveloped enteric virus. Particles are triple-layered with VP7 and VP4 (spike) forming the outer layer and mediating attachment and cell entry. VP6 forms the middle layer, which functions as an adaptor between the outer and inner layer. The inner layer is formed by VP2, which encapsidates the RNA genome. Upon cell entry, double-layered particles are observed, which are transcriptionally active and needed for proliferation. The triple- and double-layered particles have been clearly resolved via x-ray crystallography and cryo-electron microscopy, which has helped in determining the geometry of the particles. Rotaviruses have an icosahedral symmetry with different surface lattices on different layers of the particle. Channels run from the outside of the particle through the second layer and have different functions based on their size, for example the export of messenger RNA (mRNA).

The RVA genome is about 18 kb long, composed of 11 dsRNA segments and contains conserved non-coding sequences at the 5' and 3' ends required for packaging, enhancing translation, gene regulation, and replication. It encodes six structural and six non-structural proteins. Each gene segment encodes only one protein except for genome segment 11, which encodes two. In homologous strains of the virus, non-coding regions within the genes are highly conserved.

Binding and Replication

Most of what is known about the rotavirus infection cycle was learned through infection studies of monkey kidney cells or polarized intestinal epithelial cells. Infection requires the presence of exogenous proteases to cleave the outer capsid protein VP4, which initiates attachment to the host cell membrane. RV enters the host cytosol by receptor-mediated endocytosis, uncoats and viral RNA is transcribed by the viral RNA-dependent RNA polymerase (RdRp) inside the subviral particle. The positive-sense RNA serves as messenger RNA for protein synthesis and packaging into newly made double-layered particles. Within a special area of the cell, called the viroplasm, negative-sense RNA and double-stranded RNA is synthesized and the virus is packaged into these particles. Assembly is aided by intracellular calcium and particles mature *en route* to the plasma membrane. Virions are released from the host cell via cell lysis or non-lytic means. In polarized cell lines, entry and release occur primarily via the apical surface.

Pathogenesis

Rotavirus exhibits a predominant tropism for differentiated enterocytes, particularly those at the top of the villi in the small intestine, but can also infect mesenchymal cells and enterochromaffin cells. However, extraintestinal spread is also observed in humans and animal models. Infection of enterocytes can cause vacuolization, epithelial cell loss, villous blunting and crypt hyperplasia. Inflammation in the intestine is mild. In immunocompromised hosts, RV may also replicate in the liver, biliary system, and pancreas. Histological findings, severity, and exact location of infection within the intestine can vary greatly between animal species. Symptoms in animal hosts also vary greatly depending on the age of the host and the infecting virus strain. Rotavirus diarrhea is thought to occur by a combination of malabsorption as a result of enterocytes destruction and via activity of the virus-encoded enterotoxin NSP4. Release of NSP4 from an infected cell initiates a signal transduction pathway that releases intracellular calcium and chloride from neighbouring cells. In addition, virus infection of enterochromaffin cells results in secretion of serotonin, which stimulates the enteric nervous system and is thought to trigger rotavirus-induced vomiting.

Adaptive immunity is critical for protection from infection. Neutralizing antibodies against the surface antigens VP7 and VP4 are elicited by wildtype infections and a high titer of serum anti-RV IgA antibody correlates with protection from infections by the same serotype. The inner core protein VP6 is also a strong antigen but it elicits antibodies, which can neutralize the infection intracellularly, and is thought to be responsible for protection from disease, but not infection. However, since people can be re-infected with rotavirus, sterilizing immunity does not develop after a single infection and immunity wanes with age. Studies in mouse models of rotavirus infection point to a role for not only B cells but also T cells in clearing the primary infection and mediating short-term protection from re-infection. Other studies have identified VP7 neutralizing antibodies titers, intestinal, salivary or serum IgA levels as correlates of rotavirus immunity in humans. Although not fully understood, heterotypic immune responses develop during infection and are the basis for the monovalent rotavirus vaccine.

Innate immunity is critical to shape early responses to rotavirus infection. Rotaviruses are susceptible to anti-viral interferon responses and cells or calves pre-treated with interferons show reduced infection. Yet, at the same time the rotavirus non-structural protein NSP1 antagonizes the interferon response, in a species- and strain-specific manner. In general, homotypic virus strains are more effective in blocking innate immune responses than heterotypic ones. Thus, while cells sense the infection and initiate antiviral responses, the virus has developed strategies to counteract those to enable its replication.

Vaccine and Treatment

Prior to the development of a vaccine, supportive oral rehydration therapy was the preferred treatment of choice. Today, live, attenuated vaccines are available. The first rotavirus vaccine was quadrivalent and consisted of a mixture of attenuated reassortant viruses. It was developed after evidence of protection against RV was observed in response to antibodies and T cells transferred into animal models. Studies of young children showed that primary RV infection was often symptomatic and occurred very early in life, reinfections were frequent, and protection against the virus developed in association with the presence of RV antibodies. The

original vaccine was withdrawn due to adverse effects, but two new vaccines are currently in clinical use, a monovalent vaccine and a pentavalent vaccine. Both vaccines are effective in reducing the burden of RV gastroenteritis in developed countries but do not block infection and shedding. Reduced effectiveness is seen in developing countries. The reasons for this discrepancy are under investigation, as is the effect of the vaccines on genotype distribution.

Adenoviridae

Adenoviruses are double-stranded DNA viruses that cause a range of infections in humans, including respiratory disease, gastrointestinal disease and eye infections, particularly in younger hosts. While most infections are mild infections can be severe in immunocompromised patients and neonates and result in fatal pneumonia, hepatitis, or encephalitis. The *Adenoviridae* family consists of four genera: *Mastadenovirus*, *Aviadenovirus*, *Atadenovirus*, and *Siadenovirus*. Human adenoviruses (HAdV) can be found within the *Mastadenovirus* genus, while members of the other genera typically infect birds and/or reptiles. Infections are generally species-specific. At least 57 human adenovirus serotypes have been isolated and categorized into seven species or subgroups (A-G). Recombination within species is common, increasing genetic diversity. Serotypes 40 and 41 (subgroup F) are specifically associated with childhood gastroenteritis, although serotype B, C, D, and G viruses can also infect via the gastrointestinal tract, replicate there and be shed in the stool. The subgroup F adenoviruses have been less studied compared to the other HAdV due to the difficulties growing them in cell culture.

History and Epidemiology

Adenovirus was first characterized in 1953 while looking for infectious agents of respiratory disease. The incubation period of HAdV varies based on the serotype, but can range from 48 hours to two weeks. Shedding after enteric adenovirus infection lasts weeks to months. Shedding can be prolonged in immunocompromised patients, similarly to other enteric viruses. The virus can remain latent in tissues including the pharynx, intestine, urinary tract, and lymphocytes for years.

Adenoviruses are relatively resistant to UV light and thus are found widely in the aquatic environment, especially in sewage. However, chlorine disinfection is effective in eliminating infectious virus. Infections do not typically vary between seasons, unlike other enteric viruses, but do cause similar gastrointestinal symptoms. Transmission can occur after sneezing if the potential host inhales aerosolized droplets, via the fecal-oral route, or by direct exposure to mucosal membranes, blood, or tissue. Outbreaks are typically sporadic, but epidemics do occur occasionally. HAdV infects mostly infants and children and is common in places like schools, military bases, and hospitals where hosts are in close quarters. Immunocompromised patients who are infected have a higher chance of fatality and are more likely to acquire an infection after a hematopoietic stem cell or organ transplant.

Adenovirus-associated diarrhea typically occurs in children <4 years of age. Prevalence numbers vary widely depending on the location. Rates are typically between 2%–10% but as many as 38% of diarrheal cases have been attributed to Subgroup F Ads in some studies. Although these infections do not occur as frequently as rotavirus and norovirus infections, the symptoms from each virus infection are often not clinically distinguishable, and asymptomatic infections are common.

Structure

HAdV is a non-enveloped, icosahedral, double-stranded DNA virus. The capsid is ~100 nm in diameter. Fibers extending from the viral capsid engage the cellular receptor and contribute to neutralization and immune responses. The genome is approximately 36 kb long, making it one of the largest enteric viruses. More than 30 structural and non-structural proteins are encoded by the HAdV genome.

Binding and Replication

HAdV binds to target cells using the fibers that protrude from the viral capsid. Most human adenovirus types recognize the coxsackie-adenovirus receptor (CAR) protein *in vitro*, a transmembrane protein found in cells in the heart, pancreas, central and peripheral nervous system, lung, liver, and intestine. More recently, factor X has been identified *in vivo* as another receptor that bridges the interaction of the hexon with cell surface-associated heparan sulfate proteoglycans. The penton base then interacts with integrins to promote intracellular transport to the nucleus following endocytosis. Inside the nucleus, ~20 “early” viral genes are expressed first, whose gene products mediate viral DNA replication. Following replication, ~15 “late” viral genes are expressed prior to virus assembly in the nucleus. Virions are then packaged and ultimately released by cell lysis.

Pathogenesis

HAdV exhibits a tropism for many cells, including epithelial cells during an enteric infection. However, the specific tropism for Ad 40 or 41 is unknown.

Induction of type I interferons during infection is part of the host response to adenovirus. The proteins encoded by the early gene E1 and E3 encode activities to counteract host cell innate immune responses. To date, multiple mechanisms have been revealed.

They include counteracting the protein kinase R, prevention of MHC class I transport to the cell surface to evade cytotoxic T cell-mediated killing of infected cells, inhibition of tumor necrosis factor (TNF)-mediated cytolysis, and internalization and lysosomal degradation of multiple cell surface molecules, such as epidermal growth factor receptor, Fas, TNF receptor, and TRAIL receptor. While most findings were made in cell culture, limited experiments in animal models support those functions *in vivo*.

Infection with adenovirus confers life-long immunity to the infecting serotype. Adaptive immune responses are critical for this protection. Antibodies to the virus can be detected in the serum as early as 7 days post-infection, and still effectively neutralize the infection at least 10 years later. Neutralizing antibodies are directed against the three capsid proteins; the hypervariable fiber, hexon and penton base. They function extracellularly via virus aggregation, virus destabilization, blockade of virus-receptor interaction, and intracellularly by mediating proteasomal degradation or blocking microtubule spread. In addition, CD4+ and/or CD8+ T cell responses against viral capsid proteins and the DNA polymerase have also been identified and shown to be protective in humans.

Vaccine and Treatments

No specific antivirals or vaccines are available to treat adenovirus 40 and 41 infections. However, an effective oral, live adenovirus vaccine has been developed by the military against Ad 4 and Ad 7. It is given orally since the enteric infection is asymptomatic and protects well against the more severe respiratory infection typically caused by these strains. Adoptive transfer of T cells is also effective in treating Ad infections in allogeneic stem cell transplant patients. In addition, acyclic nucleosides (*e.g.*, cidofovir) are effective against many DNA viruses, including adenoviruses, since these compounds have a higher affinity for viral DNA polymerases than cellular polymerases. Multiple other antiviral compounds are effective against adenovirus infections in cell culture and animal models and may be developed into effective treatments in the future.

Adenoviruses are also being used as gene therapy vectors and account for ~25% of all gene therapy clinical trials. The beneficial aspects of these vectors include the ability to grow high titer virus stocks, the ability to infect dividing and non-dividing cells of many different cell types, and the maintenance of the vector DNA as episomes instead of chromosomal integration. While Ad 40 and 41 are not in clinical use as vectors to date, they are being developed for future use in applications that target the intestine.

The Epidemiologic Approach

Epidemiology is generally defined as the study of the distribution of disease or some other physiologic characteristic and its determinants in a population. Epidemiologists are sometimes called “disease detectives” because they identify the causes of disease or “doctors for the population” because they monitor population health, and design, implement and evaluate interventions to protect the public’s health. Even before the cause of human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) was identified, epidemiologists demonstrated that HIV/AIDS could be transmitted by sexual contact enabling the implementation of effective strategies to prevent HIV/AIDS transmission. Epidemiologic studies identified the associations of hepatitis B and human papillomavirus with cancer which led to the development of vaccines, and the efficacy of those vaccines was evaluated in epidemiologic studies, with their eventual inclusion as recommended immunizations. On a day to day basis, epidemiologists in health departments and hospitals conduct surveillance of diseases that significantly impact public health. By monitoring disease trends epidemiologists detect disease outbreaks, and evaluate the effectiveness of treatment and prevention strategies (see [Box 1](#) Epidemiologic Surveillance). Epidemiologists also investigate outbreaks, and design, implement and evaluate interventions to reduce disease occurrence. A cluster of salmonella cases? A measles outbreak? A case of meningococcus? An epidemiologist is the one leading the outbreak investigation and guiding interventions to prevent additional cases.

Epidemiologic studies characterize the natural course of a disease from onset to resolution, generate or test hypotheses about disease etiology, and identify disease outbreaks and their sources. They also describe the extent of disease in a population, and patterns and trends in disease occurrence—essential data for the development and evaluation of interventions aimed at preventing disease. Epidemiologic studies are designed to evaluate: (1) whether an individual with disease has characteristics that distinguish them from those without disease—generating or testing hypotheses about disease etiology; (2) if disease occurrence varies by time—suggesting that one or more factors might be present that enhance or decrease disease occurrence; and (3) if disease occurrence varies by geographic area—which can generate hypotheses about disease reservoirs (see [Table 1](#) for definitions of common epidemiologic terms). While the methods of epidemiology, that include study design, demography, and statistics, can be broadly applied to any feature occurring in a population, this article will focus on the application to the study of diseases caused by microbes (infectious diseases), and to microbial populations.

Understanding the natural history of infection is essential for diagnosis, treatment, and prevention of disease spread. The first step of infection is colonization: the time from colonization to disease can vary wildly, depending on the infecting organism, host characteristics, and presence of other factors. Some infections can be transmitted before the appearance of symptoms, others primarily only when symptoms are present, and others long after symptoms disappear. For example, chickenpox (varicella) is infectious 1–2 days before appearance of symptoms and lasts until the pox lesions are crusted. Following symptom resolution, varicella-zoster virus remains in the body. The latent virus can re-emerge with a different clinical presentation: shingles, which are also infectious. Many microbes that can cause infectious disease (“infectious agents”) only cause disease under certain conditions. How many individuals become ill following exposure depends on the infectious dose, the individual’s characteristics, and other factors—including the characteristics of the infectious agent. Up to 15% of the general population carries *Clostridium difficile* in their gut, however, *C. difficile* diarrhea generally only emerges following treatment with broad spectrum antibiotics ([Caroff et al., 2017](#)).

Characterizing a disease by person, place and time is a powerful method for generating hypotheses regarding the cause of disease, how it is spread, and how it might be prevented even if the cause is unknown. Dr. John Snow conducted investigations of cholera epidemics occurring in London during the 19th century. Caused by *Vibrio cholera*, cholera causes profuse watery diarrhea and vomiting leading to dehydration and shock in 5%–10% of those infected ([CDC.gov](#)). During the 19th century several waves of cholera swept Great Britain causing over 23,000 deaths in 1831–32, and at least 250,000 deaths in 1848–49. At the time cholera was defined solely by the clinical presentation. There were several hypotheses regarding the cause of cholera, but most believed that the miasma (“bad air”) theory was correct. Snow conducted a series of studies that characterized cholera cases by person, place and time; the studies’ results suggested that cholera might be transmitted by water. In London, water companies drew water from different parts of the river Thames, some upstream and others downstream of where the sewage was dumped. Water companies competed for customers - so individuals in the same city block or even the same house would buy water from different companies. Snow took advantage of this and carefully documented deaths by water company. In houses receiving water from the Southwark and Vauxhall Companies that took water downstream of the sewage there were 315 deaths/10,000 households, compared to 37/10,000 households whose water source was Lambeth Company that took water upstream. In the rest of London the rate of cholera deaths was 59/10,000 households. Most famously, in a later cholera outbreak, Snow tracked the outbreak to water obtained from a single water pump, leading to the removal of the pump handle. In this Broadstreet pump outbreak there were 127 cholera deaths over a 3 day period, and 616 deaths before the end of the outbreak. [Fig. 1](#) shows Dr. Snow’s map of the outbreak. Each bar represents a death occurring in a specific household. Note the clustering of deaths near the Broad Street pump, and that there are few or no

Box 1 Epidemiologic surveillance

In most countries, there is ongoing monitoring for diseases considered of importance. Some surveillance systems are a global effort; for example, there is surveillance worldwide for influenza (WHO.int/influenza). Influenza surveillance monitors which influenza types are circulating, and the emergence of antigenic drifts and shifts. As influenza types vary from year to year, surveillance information is critical for vaccine design, and planning for pandemics.

Components of a surveillance system include data collection, analysis and feedback, so the results can be used to describe disease trends (including identifying outbreaks), plan and target interventions, and evaluate their effectiveness. Depending on the disease there may be one or more ongoing surveillance systems. For example, the United States Centers for Disease Control and Prevention (CDC) lists seven different surveillance systems for *Salmonella* (CDC.gov/salmonella). The rate of disease from *Salmonella* serotype Typhi varies by year and age; the disease is most often detected in those aged 0–4 years (the green line in figure below). The CDC also monitors antibiotic resistance: in 1999 ~20% of *S. Typhi* was resistant to ciprofloxacin; in 2011 it was greater than 70%.

(Figure used with permission from Centers for Disease Control and Prevention (CDC) (2013). An atlas of *Salmonella* in the United States, 1968–2011: Laboratory-based enteric disease surveillance. Atlanta: US Department of Health and Human Services, CDC.)

deaths located near other water pumps (UCLA.edu). This example highlights the power of population studies to identify how a disease is transmitted—even if the transmitting agent is not known—leading to effective interventions.

When the transmitting agent is known it is easier to demonstrate transmission—especially using modern molecular techniques for strain typing. The combination of epidemiologic methods with modern molecular techniques facilitates outbreak investigations, and also provides a powerful strategy for discovering new infectious agents. During the early part of the HIV epidemic, it was observed that many individuals with AIDS had Kaposi sarcoma, a rare type of cancer. The epidemiology and natural history of the sarcoma was different from cases of Kaposi sarcoma found in individuals without HIV/AIDS. The epidemiology suggested that the sarcoma was caused by an infectious agent—but no agent could be grown using standard culturing techniques. However, using a case-control design (see Section [Epidemiologic Study Designs](#)) and molecular tools—which did not require growing the infectious agent—a virus was identified, now known as herpes simplex virus 8 or Kaposi sarcoma virus (Chang et al., 1994). Similarly, in 1977 an explosive outbreak of pneumonia occurred in Pennsylvania; as the disease occurred mainly among attendees at a convention of the American Legion, the disease was dubbed Legionnaires' disease (Fraser et al., 1977). There was no evidence of person to person spread, but the pattern of disease suggested a common-source airborne exposure. Cases of disease occurred over a relatively short period and infected individuals tended to have stayed in or visited a single hotel. This outbreak led to a successful search for the causal agent, that was named *Legionella pneumophila* in recognition of the original outbreak (Kirby et al., 1980).

Epidemiologic approaches also can provide important insights to studies of populations of microbes. While in the laboratory the microbes studied may be clonal, in vivo they are not. HIV, for example, exists in vivo as a heterogeneous, complex mixture of quasispecies with different antigenic and phenotypic properties (Santoro and Perno, 2013). Bacteria are more likely to spread clonally within an individual, but they are similarly heterogeneous at the population level. In the United States a clone of *Staphylococcus aureus*, USA300, has been a major driver of community-associated methicillin-resistant *S. aureus* (MRSA). However, whole genome sequencing of USA300 from members of two households with persistent USA300 colonization showed notable changes in the DNA of the isolates over 15 months demonstrating adaptation to individual hosts (Uhlemann et al., 2012). Further, analysis of four individuals with recurrent USA300 MRSA infection showed variability in diversity, accumulation of mutations and mobile genetic elements—and even replacement with genetically distinct USA300 MRSA strains over a 5 year period

Table 1 Definitions of common epidemiologic terms

Term	Definition
Attributable risk	Difference between the risk of disease among those exposed and risk of disease among those unexposed. A measure of the excess number of disease cases associated with exposure; or if there is a causal relationship, the excess number of disease cases attributed to exposure. Also known as the risk difference.
Case-fatality rate	Number of deaths due to a specific disease divided by the number of people with that disease. Usually expressed as a percent.
Colonization	Persistent growth of a microorganism in or on a body site that does not cause disease.
Communicable period	The amount of time when a person (or animal) can transmit the disease to another person, animal or arthropod.
Endemic	The usual frequency of a disease in a community or defined geographic area.
Epidemic	A higher than expected number of cases of a disease for a given time period and geographic area as compared with previous experience with that disease in that geographic area.
Exposure	A characteristic of a person, animal or microorganism of interest that is used to categorize a population for comparison. E.g., risk of disease among persons exposed to tobacco compared to those not exposed.
Host	The person, animal or arthropod where a microorganism usually lives or can infect under natural conditions.
Incidence	The number of new infections or disease cases in a given population per unit time; can be expressed as a probability or rate.
Incubation period	The time between exposure to an infectious microorganism and appearance of signs or symptoms of illness.
Index case	The first identified case of illness in a defined population that may infect others. Term is usually used in context of an outbreak investigation.
Morbidity rate	The number of ill persons in a defined population per unit time.
Mortality rate	The number of persons dying in a defined population per unit time.
Odds ratio	The ratio of the odds of disease among exposed divided by the odds of disease among the unexposed. Is algebraically equivalent to odds of exposure among those with disease divided by the odds of exposure among those without disease. A measure of the strength of the association between exposure and disease. The odds ratio approximates the risk ratio when disease is rare.
Pathogenicity	The proportion of colonizations that result in clinically apparent infection (disease).
Prevalence	The number of existing cases of disease divided by the number in the total population for a defined time period.
Reservoir	A person, animal or media in which a microbe normally lives and grows that can be a source of infection to another host.
Risk or rate ratio	Incidence among the exposed divided by the incidence among the unexposed. A measure of the strength of the association between exposure and disease. Also known as relative risk.
Surveillance	Ongoing, systematic collection, analysis and interpretation of health data used in the planning, implementation, and evaluation of public health programs.
Transmission	Any mechanism which can spread a microbe to another host: person-to-person direct contact, indirect contact, from mother to child during pregnancy or labor and delivery (vertical), via air, a fomite or food, or via a vector (e.g., mosquito).
Virulence	The proportion of clinically apparent infections (disease cases) that result in serious disease. The case-fatality rate is one measure of virulence.

C. and Weber, D. J. (eds.) (2001). *Epidemiologic methods for the study of infectious diseases*. New York: Oxford University Press. (3) Aschengrau, A., Seage, G. R. (2014). *Essentials of epidemiology in public health*. Burlington: Jones & Bartlett Learning.

(Azarian et al., 2016). This underscores the necessity of evaluating claims about the contribution of particular clones or genes to disease pathogenesis by using population-based samples, proper study design and examination of the role of cofactors and confounders. An illustrative example of this phenomena is the putative association of Panton-Valentine leucocidin (PVL) toxin with poorer clinical outcomes from invasive disease caused by MRSA. This putative association seems to have resulted from the strong correlation between PVL and MRSA in the United States. Analyses of strains from Europe where most PVL are methicillin sensitive, and from Australia where half of community MRSA clones are PVL-positive but much of PVL-positive disease is caused by methicillin sensitive *S. aureus* do not support an association of PVL with poorer clinical outcomes (Shallcross et al., 2013). This is not to say that PVL is not a virulence factor (see, for example, Bamberger, 2017; Prince et al., 2017), but the amount of severe disease caused by MRSA that is attributable to PVL alone—and thus the importance of developing specific therapies against PVL, is likely not as extensive as previously believed.

In summary, the epidemiologic approach is characterized by examining variations in population distributions. Epidemiologic surveillance is a cornerstone of public health, used to monitor population health for outbreaks and evaluate the effectiveness of interventions. Epidemiologic studies are conducted to identify causes of disease outbreaks, generate and test hypotheses about disease etiology and transmission, and evaluate the effectiveness of interventions.

Epidemiologic Study Designs

Studies in human populations are very challenging: humans vary in genetic background, behavior and environment. Large sample sizes are needed for study so variations that might modify or obscure an association can be taken into account in the analysis. Further, humans may choose whether to participate in a study, and whether to complete the entire study protocol. These choices

Fig. 1 Dr. John Snow's map of the cholera outbreak. Each black bar represents a death occurring in a specific household. Note the clustering of deaths near the Broad Street pump (*gold star*), and that there are few or no deaths located near other pumps (UCLA.edu).

may bias any observed associations and limit the generalizability of study results. Even in animal models using clonal lineages, it can be challenging to design experiments to eliminate all extraneous factors, so that the signal of an association between an exposure and outcome of interest (if it exists) can be identified, for example, cage effects. Clinical trials, experiments conducted in human populations, are usually much larger than similar experiments in animal systems because of the inherent variability in study participants. Further, it is not considered ethical to test a treatment in humans unless there is strong evidence that it might be more effective than standard of care. Therefore, because of these and other challenges (e.g., cost) a majority of epidemiologic studies are observational. Although the investigator does not assign individuals to exposure or treatments in an observational study, a carefully designed epidemiologic study can approximate an experiment (see [Table 2](#) for a description of epidemiologic study designs). The design closest to an experiment is a cohort study where the investigator follows individuals that vary in the exposure(s) of interest until the outcome of interest occurs.

Cohort studies vary in size and purpose. Cohorts are designed to describe the natural history of disease, and to estimate the strength of association between one or more exposures and one or more outcomes of interest, for example, as a follow-up to outbreak investigation (see [Box 3](#) in Section [Outbreak Investigations](#)). Because participants are sampled by their exposure status, cohort studies are ideal for evaluating the effects of rare exposures. Mounting and maintaining a study cohort is very expensive and therefore often are used to explore a variety of exposures and outcomes. There are several, ongoing, large, long-term cohort studies.

(2015). *Relationship between Guillain-Barré syndrome, influenza-related hospitalizations, and influenza vaccine coverage*. *Vaccine* **33**, 2045–2049.

Table 2 Characteristics of epidemiologic study designs, from most to least definitive

Design	Sampling for inclusion	Timing of measurement	Parameters that can be estimated	Purpose
Experiment	By population	Individual: multiple time points	● Incidence ● Risk or rate ratio, odds ratio	● Hypothesis testing
Cohort	By exposure or population	Individual: multiple time points	● Incidence rate ● Prevalence of disease or exposure ● Risk or rate ratio, odds ratio ● Attributable risk	● Hypothesis testing ● Hypothesis generating
Case Control	By disease (outcome)	Individual: single time point	● Odds ratio	● Hypothesis testing ● Hypothesis generating
Cross-sectional	By exposure, disease (outcome) or population	Individual: single time point	● Prevalence of disease or exposure, prevalence odds ratio ● Point prevalence ratio	● Descriptive ● Hypothesis generating
Ecological	By exposure, disease (outcome) or population	Groups: (e.g., neighborhood, factories, cities, counties, countries): single or multiple time points	● Correlation coefficient	● Hypothesis generating of population-level effects

Two of the best known are the Framingham Heart Study [www.framinghamheartstudy.org], begun in 1948 to study risk factors for heart disease, and the Nurses' Health Study [www.nurseshealthstudy.org], begun in 1976 to investigate the potential long-term effects of using oral contraceptives. Framingham originally enrolled 5209 men and women aged 30–62 living in Framingham Massachusetts; subsequently the original participants' children and grandchildren were enrolled. Participants complete a physical examination, questionnaires on medical history and life style, and laboratory tests every 2 years. The study has yielded over 3500 papers on the risk factors for and genetics of heart disease and related conditions. The Nurses' Health Study has enrolled over 280,000 nurses in three waves. Cohort members complete a questionnaire every 2 years about medical history and lifestyle variables, including diet. Biological specimens have been collected from a subset of the study participants. Hundreds of publications on topics ranging from effects of diet and exercise on cancer risk to rotating night shift work and heart disease have resulted.

In a case-control study, participants are sampled by the presence and absence of the outcome of interest and the investigator compares the frequency of exposure among those with and without the outcome. Cheaper to conduct than a cohort study, case-control studies often are used as part of outbreak investigations (see Box 3 in Section Outbreak Investigations). Other applications are studies of rare outcomes, as it is more efficient to compare cases with a sample of controls than to follow a cohort of 10,000 for something that occurs only in one out of a thousand individuals.

Cross-sectional studies describe the distribution of outcome and exposure at a single point in time. Cross-sectional studies are used to allocate resources, plan interventions and future cohort studies, and to generate hypotheses. Ecologic studies compare frequency of exposure and outcome among populations, rather than individuals (see Box 2).

Identifying naturally occurring events that facilitate answering research questions of interest and designing appropriate studies to address those questions is a major component of epidemiologic research. Outbreak investigations, for example, are excellent opportunities to gain new knowledge regarding the factors that influence transmission of infectious agents. The investigation of an outbreak starts with description and usually ends with conducting a case-control or cohort study or both.

Outbreak Investigations

The first step in an outbreak investigation is verifying that there is an outbreak. An outbreak or epidemic is defined as a significant increase in the number of cases of a particular disease occurring in a given geographic area for a defined time period. This entails describing the incidence rate, the number of new cases that occur over a defined time period, and comparing it to historical rates in the same population (see Table 1 for definitions of common epidemiologic terms). If the incidence rate significantly exceeds that expected for a given time period an outbreak is suspected. As measles has been eradicated in North America, a single case of measles is considered an outbreak; introduction of a new organism, for example, an antibiotic resistant organism with resistance caused by a mechanism infrequently reported in a geographic region, is also an outbreak. Assuming that the increase in cases is not due to increased testing or a change in diagnostic procedures, the next step is determining the extent of the outbreak by conducting a field investigation. A case definition is established, and then the investigator uses various methods to identify any additional cases. Methods of case finding range from reviewing medical records, calling attendees at the event associated with the outbreak, to advertising in the media. Identified cases are described by person, place and time characteristics. For outbreaks caused by microbes, strain typing information can be very important, as the increase in cases might be associated with a more virulent strain, but also might be associated with a breakdown in sterile hygiene or some other factor. If the excess of cases are all of a single strain the strain type might be used in the case definition, which increases the power of the study to identify the factor(s) that led to the outbreak. Descriptive analysis usually leads to working hypotheses about the outbreak cause which are used in the next steps of the investigation.

Following description, the investigator has a choice of study design (see Table 2 for a comparison of study designs). A cohort study is optimal if feasible. The cohort for an outbreak investigation consists of all those who were at risk of the outcome of interest. For an outbreak investigation of foodborne illness, say at a picnic, this would entail talking to everyone who attended the picnic and asking what foods they ate. The incidence of disease by exposure to various foods is calculated, and the attack rates by food are compared. As it can be challenging (and costly) to identify and contact everyone attending an event, an alternative strategy is to conduct a case-control study. The investigator identifies those meeting the case definition and compares them to a sample of those without disease but who were at risk (controls); for a picnic, controls would be picnic attendees who did not get sick. One or more controls can be selected per case. A key criteria for control selection is that they stem from the same underlying population from which the cases arose. Ideally, they would be a sample of the entire population at risk of outcome (see Further Readings for a more detailed discussion). Proper control selection is essential to minimize bias. Cohort and case-control designs provide complementary information, and both might be applied in an outbreak.

As an illustration of outbreak investigation and subsequent studies see the diagram in Box 3. After observing the occurrence of 6 cases of Delhi Metallo- β -Lactamase-Producing Carbapenem-Resistant *Escherichia coli* (NDM) in a tertiary facility several investigations were conducted (Epstein et al., 2014). At the time, a single occurrence of NDM was considered worthy of investigation to prevent transmission. After confirming the presence of NDM, investigators identified cases from clinical cultures, and performed rectal screening of cases' roommates, and patients admitted to the ward where the first patient was treated. They reviewed medical records to generate hypotheses. History of procedures using a duodenoscope was common among initial cases. Investigators then randomly selected controls from patients who had negative rectal screening cultures. After finding that cases were 78 times more

Box 2 Ecologic studies

In an ecologic study the unit of analysis is a population, e.g., a town, city, county or country. These studies generally use existing data (often collected for other purposes) to generate or test hypotheses. Correlations between population trends in disease and exposure should be interpreted with caution, but can be very useful. For example, in the 1950s, a ground breaking study by Doll and Hill showed a strong correlations between increasing tobacco use since the early 1900s and incidence of lung cancer (Doll and Hill, 1950). For some hypotheses, such as changes in disease rates by weather patterns or population-level interventions (e.g., imposing taxes to decrease consumption), an ecologic study is the only feasible method of assessing an effect. For example, Iqbal et al. demonstrated a relationship between hospitalization for pneumonia and influenza and hospitalizations for Guillain-Barre syndrome, the most common cause of acute flaccid paralysis (Iqbal et al., 2015) (Fig. 2).

Box 3 Outbreak investigation

Diagram of investigation of an outbreak of New Delhi Metallo- β -Lactamase-Producing Carbapenem-Resistant *Escherichia coli* (NDM) in a tertiary care facility (Epstein et al., 2014).

likely than controls to have undergone a procedure using a duodenoscope, the hospital notified all patients who had undergone a procedure using a duodenoscope and offered rectal screening. Duodenoscopes were cultured and compared to the isolates from cases using pulsed-field gel electrophoresis (PFGE). A single duodenoscope was implicated. All patients exposed to this duodenoscope were included in a cohort study, to identify what specific procedures were associated with increased risk of NDM transmission. After implementing a change in cleaning procedures, no further cases were identified.

Summary

The epidemiologic approach provides a powerful strategy for solving complex problems and evaluating potential solutions. Ongoing epidemiologic surveillance provides essential information for making health decisions for public health practitioners, clinicians and the public. Epidemiologic training includes study design, statistical methods, the biological basis of disease and the contribution of social factors to disease etiology. The methods are inherently interdisciplinary, integrating multiple perspectives to understand disease patterns and their determinants. Epidemiology is a key component of training for public health practitioners, infection preventionists, directors of clinical microbiology laboratories, and physicians specializing in preventive medicine, infectious diseases or antibiotic stewardship.

Introduction

First described by Theodor Escherich from stool samples of healthy infants in 1885, *Escherichia coli* (formerly *Bacterium coli* and *Bacillus coli*), a Gram-negative facultative anaerobic nonspore-forming motile rod, has undergone considerable changes in its profiles during the subsequent decades. From an innocuous intestinal commensal to an important pathogen of both humans and animals, pathogenic *E. coli* is now known to cause a spectrum of clinical diseases in human and animal hosts, including urinary tract infection (UTI, which may sometimes evolve to haemolytic-uremic syndrome or HUS), blood and central nervous system infections (sepsis/meningitis), and gastroenteric infection.

Taxonomy

Escherichia coli is classified taxonomically in the genus *Escherichia* (named after its discoverer Theodor Escherich), family Enterobacteriaceae, order Enterobacteriales, class Gammaproteobacteria, phylum Proteobacteria. Currently, the genus *Escherichia* comprises five recognised species: *E. albetii*, *E. coli* (the type species), *E. fergusonii*, *E. hermannii* and *E. vulneris*. Two former *Escherichia* species, *E. adecarboxylata*, and *E. blattae*, have been reclassified as *Leclercia adecarboxylata* and *Shimwellia blattae*, respectively.

On the basis of its surface antigens (i.e., somatic O antigen and flagellar H antigen), *E. coli* can be separated into >190 serogroups (serotypes), with the serotype of an *E. coli* isolate being defined by a specific combination of O-and H-antigens (e.g., O157:H7). In many cases, the O-antigen (which forms part of lipopolysaccharide layer) is 'masked' by a heat-labile, acidic polysaccharide capsule (K-antigen). Specific serogroups are often associated characteristically with certain clinical syndromes, but some may be implicated in more than one category of *E. coli* pathotypes.

Using genotyping techniques, *E. coli* may be distinguished into six phylogenetic groups (A, B1, B2, D, E, and Shigella). Despite its close association with other members of *E. coli*, and possibly representing the clones of *E. coli*, the phylogenetic group Shigella has continued to be treated as a separate genus *Shigella* (which includes the species of *S. dysenteriae*, *S. flexneri*, *S. boydii*, *S. sonnei*) due to historic considerations.

In accordance with its pathogenic potential, *E. coli* is divided into non-pathogenic and pathogenic groups. Although the non-pathogenic *E. coli* exists as a commensal in the intestine of warm-blooded animals, it may be involved in opportunistic infections at times. The pathogenic *E. coli* is responsible for three main types of disease in humans: urinary tract infection (UTI, which may sometimes evolve to haemolytic-uremic syndrome or HUS), blood and central nervous system infections (sepsis/meningitis), and gastroenteric disease.

Through their unique interactions with eukaryotic cells, adhesion/colonization mechanism, toxin/virulence factor production and clinical disease profiles, the pathogenic *E. coli* strains are further distinguished into ten pathotypes: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroaggregative *E. coli* (EAEC), Shiga-toxin-producing enteroaggregative *E. coli* (STEAEC), enteroinvasive *E. coli* (EIEC), diffusely adhering *E. coli* (DAEC), adherent invasive *E. coli* (AIEC), uropathogenic *E. coli* (UPEC) and meningitis-associated *E. coli* (MAEC) (Table 1). Collectively, ETEC, EPEC, EHEC, EAEC, STEAEC, EIEC, and DAEC are known as diarrhoeagenic *E. coli*, while AIEC is enteric pathogen causing Crohn disease in which diarrhoea may present as one of the symptoms.

Interestingly, while some diarrhoeagenic *E. coli* prefer the sparsely colonised small bowel as their preferred site of infection (ETEC, EPEC), others execute their pathogenic strategies at the level of the colonic mucosa (EIEC, EHEC and probably EAEC), in more intimate-proximity to the enterocyte than non-pathogenic flora. Furthermore, whereas EHEC, EPEC and EIEC rely on type 3 secretion system (T3SS) to translocate bacterial proteins (known as effectors) directly into the eukaryotic host cell in order to subvert host cell processes, ETEC, EAEC, STEAEC, DAEC and AIEC are non-T3SS dependent pathotypes, which have comparatively simple and efficient molecular mechanisms of virulence requiring effective colonization factors followed by secretion of toxins that subsequently enter the host cell.

Structural and Genomic Characteristics

E. coli possesses a number of structural and genomic features that are important for maintaining its life cycle, and for invading and surviving inside host cells.

☆Change History: August 2014. Version 2009, M Schaechter (San Diego State University, San Diego, CA, USA); Version 2014, D Liu (RCPAQAP, NSW, Australia).

This article is an update of M. Schaechter, *Escherichia coli*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 125–132.

Table 1 Classification and characteristics of *E. coli* pathotypes

Category	Serogroups ^a	Toxin	Adhesin	Clinical disease
Enterotoxigenic (ETEC)	Chiefly O6, O8, O15, O20, O25, O27, O63, O78, O80, O85, O115, O128ac, O139, O148, O153, O159, O167 among 117 serogroups	Heat-labile enterotoxin (LT), Heat-stable enterotoxin (ST), Cytolysin A (ClyA)	Colonization factors (CF), Porcine A/E associated adhesin (Paa)	Acute watery diarrhoea (<5 yo) Travelers' diarrhoea
Enteropathogenic (EPEC)	O26, O55, O86, O111, O114, O119, O125, O126, O127, O128, O142, O158	-	Intimin, Bundle forming pili (BFP) Paa, LPF, Iha, EhaA	Infant diarrhoea
Enterohemorrhagic (EHEC)	O26, O91, O111, O157	Stx	Intimin, Paa, Toxin B (ToxB), <i>E. coli</i> factor for adherence (Efa)-1, LPF, STEC autoagglutinating adhesin (Saa), <i>E. coli</i> immunoglobulin-binding protein (EibG), EHEC autotransporter encoding gene A (EhaA), Outer membrane protein A (OmpA), Iha	Food poisoning (Haemorrhagic colitis or bloody diarrhoea, HUS)
Enteroaggregative (EAEC)	O3, O15, O44, O77, O126	EAEC heat-stable enterotoxin 1 (EAST1), Shigella enterotoxin (ShET)1, Haemolysin E (HlyE)	Aggregative adherence fimbriae (AAF) (I, II, III, Hda), Toxigenic invasion loci A (Tia)	Travelers' diarrhoea, Infant diarrhoea
Shiga-toxin-producing enteroaggregative (STEAEC)	O114	Stx	AAF, IrgA homolog adhesin (Iha)	Food poisoning
Enteroinvasive (EIEC)	O28ac, O29, O112ac, O124, O136, O143, O144, O152, O164, O167	ShET1/2	-	Shigellosis
Diffusely adherent (DAEC)	O86, O127, O142, O158 (isolated from children and containing Afa/Dr genes)	-	afimbrial (Afa) or fimbrial (Dr) adhesins	Acute diarrhoea (<5 yo)
Adherent invasive (AIEC)	O6, O25, O83	-	Type 1 pili, long polar fimbriae (LPF)	Crohn's disease, with a chronic transmural, segmental, and typically granulomatous inflammation of the intestine
Uropathogenic (UPEC)	O1, O2, O4, O6, O7, O8, O16, O18, O25, O75, O78, O114, O142, O164, O157	α -Haemolysin, Cytotoxic necrotizing factor 1	P fimbriae (coded by <i>pap</i>), S fimbriae (coded by <i>sfa</i>), Afa adhesions (coded by <i>afa</i>)	Asymptomatic bacteriuria, cystitis, pyelonephritis, septic shock
Meningitis-associated (MAEC)	O1, O2, O18, O45, O83	-	P fimbrial adhesin, S fimbrial adhesin	Fever, irritability, seizures

^aETEC, EPEC, EHEC, EAEC, STEAEC, EIEC, and DAEC are collectively known as diarrhoeagenic *E. coli*. Some serogroups are associated with more than one diarrhoeagenic disease category. For example, although serogroup O86 is mainly considered as EPEC, it has also been implicated in ETEC, EAEC, and DAEC infections.

Pathogenesis of adherent-invasive *Escherichia coli*. Future Microbiology 2013;8:1289–300.

Fimbriae (Pili)

E. coli strains have one or two kinds of fimbriae, common and conjugative (sex pili). Common fimbriae (numbering 100–1000 per cell) are mainly composed of an acidic hydrophobic protein called fimbrin. According to the amino acid sequence of their major fimbrin, common fimbriae are separated into seven groups. Fimbriae are highly antigenic, comprising many F antigens. It is notable that *E. coli* strain K12 contains only type 1 common fimbriae, and it may alternate between the fimbriated and nonfimbriated condition, a phenomenon known as phase variation. This may be due to the possibility that the presence of common fimbriae allows organisms in their first efforts to colonize their host by attaching to epithelial cells. Inside the body, turning off the synthesis of common fimbriae may lessen the chances that the organisms will be phagocytized by white blood cells.

The sex fimbriae (usually called pili, with one or a few copies per cell) are encoded by plasmids such as F or R. These structures cause the donor and recipient bacteria to make contact, allowing the transfer of DNA during conjugation.

Flagella

E. coli possesses 5–10 flagella per cell, which are responsible for its motility. The flagella are typically 5–10 µm-long and are arranged randomly around the cell surface, a pattern called peritrichous flagellation. Structurally, *E. coli* flagella are composed of a long filament, a hook, and a basal body, with an *N*-methyl-lysine-rich protein (55 kDa in size) known as flagellin being the principal component. Around 20 000 subunits of this protein assemble to make the flagellar filament. *In vitro*, flagellin self-assembles into flagella-like filamentous cylindrical lattices with hexagonal packing.

The *E. coli* flagellar genetic system consists of about 40 genes arranged in five regions. These genes are involved in structure, function, assembly, and regulation. Flagella are highly antigenic, comprising a large number of H antigens, with the N- and C-termini of various H antigens being highly conserved.

Capsule and Outer Membrane

The outer membrane of some *E. coli* strains is covered by a polysaccharide capsule composed of K antigens. Other polysaccharides, the M antigens (colanic acids, which are polymers of glucose, galactose, fucose, and galacturonic acid), are synthesized under conditions of high osmolarity, low temperature, and low humidity. Additionally, *E. coli* has a glycolipid anchored in the outer leaflet of its outer membrane, called the enterobacterial common antigen (ECA). The outer membrane of *E. coli* consists of a lipid bilayer whose inner leaflet is made up largely of phospholipids and whose outer leaflet is made of lipopolysaccharide (LPS). Interspersed are several kinds of membrane proteins.

One membrane protein, the murein lipoprotein, is small (7.2 kDa), with 7×10^5 copies per cell. This protein contains three fatty acid residues that help anchor it into the inner leaflet of the outer membrane, whereas the rest of the molecule is located in the periplasm. About one-third of the molecules are covalently linked to the cell-wall peptidoglycan. The major outer-membrane proteins include the pore-forming proteins, called porins Omp C, Omp F, and Pho E. Together, these porins are present in about 10^5 copies per cell. Their sizes vary from 36.7–38.3 kDa. The diameters of the pores are 1.16 nm for Omp F and Pho E and 1.08 nm for Omp C. Synthesis of Omp F is repressed by high osmotic conditions or high temperature, that of Omp C is depressed by high osmotic conditions, and Pho E is synthesized when cells are starved for phosphate.

Certain compounds that are too large to diffuse through *E. coli* porin channels are carried across the outer membrane by special transport proteins. These compounds include maltose oligosaccharides, nucleosides, various iron chelates, and vitamin B12. The proteins involved, as well as the porins, also act as receptors for the attachment of bacteriophage and colicins.

Periplasm and Cell Wall

The periplasm (the space between the inner and outer membranes) of *E. coli* makes up 20–40% of the cell volume. This compartment is osmotically active, in part because it contains large amounts of membrane-derived oligosaccharides (molecules of 8–10 linked glucose residues substituted with 1-phosphoglycerol and O-succinyl esters). The *E. coli* periplasm contains over 60 known proteins, including binding proteins for amino acids, sugars, vitamins, and ions; degradative enzymes (phosphatases, proteases, and endonucleases); and antibiotic detoxifying enzymes (β -lactamases, alkyl sulfodehydrases, and aminoglycoside phosphorylating enzymes). The periplasmic environment is oxidizing, whereas that of the cytoplasm is reducing. This explains why certain secretory proteins that require disulfide bonds for activity are inactive in the cytoplasm. The cell wall of *E. coli* consists of a peptidoglycan layer responsible for cell shape and rigidity. The peptidoglycan layer (of one or a few molecules thick) is anchored to the outer membrane at some 400 000 sites via covalent links to the major membrane lipoprotein and noncovalent links to porins. The periplasm is spanned by 200–400 adhesion zones between the outer membrane and the cytoplasmic membrane. These appear to be the sites of attachment of certain bacteriophage and of export of outer-membrane proteins and lipopolysaccharide. In addition to these apparently scattered junctions, the two membranes appear joined at defined periseptal annuli, ring-shaped adhesion zones that are formed near the cytoplasmic membrane.

The cytoplasmic membrane of *E. coli* is made up of about 200 distinct proteins and four kinds of phospholipids. Proteins make up about 70% of the weight of the structure. Under aerobic conditions, the *E. coli* cytoplasmic membrane contains a number of dehydrogenases (e.g., NADH-, D- and L-lactate, and succinate dehydrogenases), pyruvate oxidase, cytochromes (of the o and d complexes), and quinones (mainly 8-ubiquinone). Anaerobically grown *E. coli* may contain other dehydrogenases (e.g., formate and glycerol-3-phosphate dehydrogenases) and enzymes involved in anaerobic respiration (nitrate and fumarate reductases). The cytoplasmic membrane is the site of adenosine triphosphate (ATP) synthesis. The cytoplasmic membrane systems involved in the transport of solutes are highly efficient and enable its growth in relatively dilute nutrient solutions. The cytoplasmic membrane of *E. coli* contains over 20 proteins involved in various aspects of peptidoglycan biosynthesis, cell wall elongation, and cell division. About 10 of these proteins have been identified by their ability to covalently bind β -lactam antibiotics. They are known as the penicillin-binding proteins, and some have been shown to be involved directly in cell-wall synthesis.

Cytoplasm

Biochemical reactions necessary for the growth of *E. coli* mostly take place in the cytoplasm. These activities are divided into those concerned with metabolic fueling (production of energy, reducing power, and precursor metabolites), biosynthesis of building

blocks, polymerization into macromolecules, and assembly of cell structures. In fast-growing *E. coli*, much of the cytoplasmic space is taken up by ribosomes. The number of ribosomes per cell is proportional to the growth rate, ranging from about 2000 in cells growing at 37 °C peptidoglycan layer peptidoglycan layer at doubling rates of 0.2 per hour to >70 000 at a doubling rate of 2.5 h per hour, where they make up about 40% of the cell mass. In *E. coli*, the genes for the four ribosomal RNAs (16S, 23S, 5S, transfer) are arranged in seven operons located at different sites on the chromosome.

Most of these operons are found near the origin of chromosome replication and, thus, are replicated early. This arrangement ensures that ribosomal RNAs are made in large amounts during rapid growth. Each operon encodes one, two, or three transfer RNAs at sites between the 16S and 23S RNA genes or at the end of the operon. The 52 ribosomal proteins are encoded by 21 transcriptional units. Ribosomal RNAs and proteins assemble into particles via a precise sequence of reactions that has been well studied *in vitro*.

Genome and Nucleoid

The *E. coli* strain MG1655 (a laboratory strain K-12 derivative) genome consists of a circular DNA molecule of 4.64 Mb in length, with 4288 protein-coding genes (organized into 2584 operons), seven ribosomal RNA (rRNA) operons, and 86 transfer RNA (tRNA) genes. It also includes a significant number of transposable genetic elements, repeat elements, cryptic prophages, and bacteriophage remnants. The genomes of some pathogenic *E. coli* are about 1 Mb larger than that of the commensal K-12 strain, as exemplified by enterohaemorrhagic *E. coli* strains O157:H7 Sakai (5.50 Mb); enteroaggregative *E. coli* strain O42 (5.36 Mb) and UPEC isolates CFT073 (5.23 Mb), 536 (4.94 Mb), UTI89 (5.07 Mb). The extra genetic segments were probably acquired by horizontal gene transfer.

Comparative analyses of *E. coli* and *Shigella* genomes indicate that the predicted pan-genome consists of 15 741 gene families, and only 993 (6%) of the families are found in every genome, comprising the core genome. The variable or 'accessory' genes account for >90% of the pan-genome and about 80% of a typical genome. The plasticity of the *E. coli* genome is conferred mainly by two genetic configurations, virulence-related plasmids and chromosomal pathogenicity islands. Although many strains (e.g., strain MG1655) do not contain plasmid, some may possess 1–5 plasmids in their genome. All seven categories of diarrhoeagenic *E. coli* carry at least one virulence-related property on a plasmid. In the case of EIEC, EHEC, EAEC and EPEC, a member of a highly conserved plasmid family is often present. Encoding multiple virulence factors, the plasmid is typically large (>60 megadalton or MDa), of low copy number, and either conjugative or of transmissible incompatibility group. While clusters of virulence traits are encoded plasmids and pathogenicity islands, individual traits (e.g., shiga toxin) may be encoded by transposons.

Similar to other bacteria, the *E. coli* genome is condensed into a compact structure called the nucleoid. Nucleoid activities such as transcription, replication, recombination, and repair are influenced by the structural properties and the special conformations of nucleoid. The nucleoid of *E. coli* is a highly lobular intracytoplasmic region, generally located toward the center of the cell. In this region, the DNA is found at a local concentration of 2–5% (w/v). *In vivo* the DNA is negatively supercoiled into some 50 individual domains. Transcription takes place at the nucleoid–cytoplasm interface, as the nucleoid forms a significant barrier to the diffusion of many macromolecules. The highly irregular shape of the nucleoid may contribute to the availability of genes for transcription. At least four small-molecular-weight proteins that bind to DNA are known to play a role in transcription, recombination, and replication. These nucleoid-associated proteins range in molecular weight from 9.2 to 15.4 kDa. Two, HU and IHF, are among the abundant *E. coli* proteins and are present in 20–50 000 monomers per cell.

The initiation of DNA replication takes place at a specific origin site, *oriC*, and is under the influence of a protein that is highly conserved among many bacteria, DnaA. Once initiated, DNA replication takes place at a nearly constant rate in moderately fast and fast-growing *E. coli*, until it reaches a terminus. Segregation of the nucleoids takes place with considerable fidelity and, thus, cannot result from partitioning into progeny cells by chance alone. *In vitro*, recently replicated (hemimethylated) origin DNA binds to the membrane with great specificity.

Biology and Epidemiology

Biology

The central metabolism of *E. coli* is conducted via the Embden–Meyerhof–Parnas pathway, the pentose pathway, the tricarboxylic acid cycle, and the Entner–Doudoroff pathway (for the metabolism of gluconate). As a facultative anaerobe, *E. coli* fulfils its energy needs by either respiratory or fermentative pathways. Under anaerobic conditions, the main products are formate, acetate, lactate, succinate, ethanol, 2,3-butanediol, CO₂, and H₂. Its need for biosynthetic building blocks is met by the production of 12 precursor metabolites common to all bacteria. *E. coli* has a complete system of transporting and using organic phosphates, including an inducible alkaline phosphatase in its periplasm.

E. coli is a chemoheterotroph with the capability to grow on any of a large number of sugars or amino acids provided individually or in mixtures. Some strains found in nature have single auxotrophic requirement such as thiamin. The growth of many strains is inhibited by the presence of single amino acids, such as serine, valine, or cysteine. *E. coli* grows faster with glucose than with any other single carbon and energy source and reaches a doubling time of 50 min under well-oxygenated conditions at 37 °C. Slow rates of growth can be achieved by using an externally controlled continuous culture device or by adding a metabolic analogue and its antagonist to the culture at proper ratios. *E. coli* grows more rapidly in rich-nutrient broths (containing amino acids, nucleosides, sugars, and vitamin precursors, etc.), reaching doubling times of 20 min at 37 °C. *E. coli* can grow at temperatures between 8 and

48 °C, depending on the strain and the nutrient medium. Its optimum growth temperature is 39 °C. *E. coli* does not grow in media containing a NaCl concentration greater than about 0.65 M. In response to changes in the osmotic pressure of the medium, *E. coli* increases its concentration of ions, especially K⁺ and glutamate. The pH range for growth is between pH 6.0 and 8.0, although some growth is possible at values approximately 1 pH unit above and below this range.

Epidemiology

E. coli is well adapted to colonizing the mammalian intestine and seldom causes disease. It colonizes not only the large intestine of vertebrates but also the ileum, the distal segment of the small intestine. In the ileum, *E. coli* may have been selected for rapid growth under oxygenated conditions; in the colon, in competition for limited nutrients and in the presence of noxious chemicals under anoxic conditions. When human strains are cultivated in the laboratory, they tend to lose the ability to colonize. Included among these is K12, the most widely used laboratory strain in the molecular microbiology.

Periodically deposited from their intestinal residence into soils and waters, *E. coli* bacteria do not survive for extended periods of time in such environments and could be cultured only for a few days (seldom weeks) after their introduction. For this reason, their presence has been taken as a measure of recent fecal contamination, and the coliform count of the drinking water supply or of swimming facilities is still a common measure of microbiological water purity.

Mammals become colonized with *E. coli* within a few days of birth, possibly during passage through the birth canal or, shortly after birth, via the fecal–oral route from the mother or other attendants.

Primary reservoir of UPEC isolates is within the human intestinal tract. Two important routes by which UPEC bacteria can invade and spread within the urinary tract are the ascending and haematogenous pathways. Ascending route is a widely accepted paradigm of infection, which involves the ascension of bacteria from the gut microbiota to the vagina and then the bladder i.e., the faecal–perineal–urethral pathway and rectal flora serving as reservoir for the strains infecting the urinary tract. Uropathogens gain entry into the bladder, by means of the urethral massage that may accompany sexual intercourse. Once the bacteria ascend into the bladder, they may multiply and pass up the ureter, particularly if vesicoureteral reflux is present, and then to the renal parenchyma. The subsequent development of infection depends upon the particular organism, the inoculum size and the adequacy of host defences. Haematogenous route facilitates infection of the renal parenchyma by blood-borne organisms.

Clinical Features

E. coli strains are responsible for a large number of clinical diseases in humans, with the most common infections involving the intestinal and urinary tracts, leading to watery diarrhoea or locally invasive forms of infection (e.g., dysentery). *E. coli* infects deeper tissues, including the blood (septicemia) as a complication of focal extraintestinal infections such as pyelonephritis and, meningitis in newborns.

ETEC

Usually acquired from food or water contaminated with human or animal feces, enterotoxigenic *E. coli* (ETEC) induces watery diarrhoea of varying severity (ranging from mild, self-limiting disease to severe cholera-like, life threatening illness). Beginning with a sudden onset of watery stool (without blood or inflammatory cells), and vomiting, the disease may present with dry mouth, rapid pulse, lethargy, decreased skin turgor, decreased blood pressure, muscle cramps, and shock as a result of progressive loss of fluids (dehydration) and electrolytes (sodium, potassium, chloride, and bicarbonate). Lasting for only 3 to 4 days, the diarrhoea is self-limited; if hydration is maintained, the patients survive, without any sequelae. Besides diarrhoea in infants younger under 2 years of age in the developing world, ETEC is also associated with travellers' diarrhoea.

EPEC

Enteropathogenic *E. coli* (EPEC) is a common cause of watery diarrhoea among infants in the developing world, and is also responsible for sporadic diarrhoeal outbreaks among infants in the developed world. In addition to watery diarrhoea containing mucus but not blood, other symptoms such as vomiting, fever, malaise and dehydration may be present. These symptoms may persist for several days but chronic EPEC has been also observed. EPEC may sometimes cause bloody diarrhoea after the colonization of the mid-distal small intestine (ileum). This pathotype induces a characteristic attaching/effacing (A/E) lesion on intestinal epithelium, without the production of Shiga toxins. Two groups of EPEC have been recognised: typical EPEC (tEPEC) strains (including classical O26, O55, O86, O111, O119, O125, O126, O127, O128ac, O142, O158), and atypical EPEC (aEPEC) strains, which lack the EPEC adherence factor plasmid (or pEAF) but contain other virulence factors.

EHEC

Enterohaemorrhagic *E. coli* (EHEC) typically causes an afebrile bloody colitis (bloody stools with ulcerations of the bowel) known as hemorrhagic colitis. In about 10% of patients (e.g., children and the elderly), infection with EHEC O157 may result in haemolytic

uraemic syndrome (HUS), which is defined by acute renal failure, haemolytic anaemia and thrombocytopenia. Like EPEC, EHEC elicits an attaching and effacing lesion of the intestinal mucosa, this time of the colon. The elaboration of an oligomeric Shiga toxin (Stx1 or Stx2) contributes to the haemorrhagic colitis and to the development of the systemic sequelae of disease. Because its cytotoxins closely resemble the Shiga toxin produced by *Shigella dysenteriae* 1 (Stx1 and Stx2), EHEC is also known as Shiga toxin-producing *E. coli* (STEC).

EAEC

Enteraggregative *E. coli* (EAEC) infection manifests clinically by a watery diarrhoea with or without blood and mucus, abdominal pain, nausea, vomiting, and low-grade fever. EAEC can cause both an acute and a chronic (> 14 days) diarrhoeal illness. Malnourished hosts may be unable to repair mucosal damage, and thus prone to persistent or chronic diarrhoea. Without enterotoxins LT or ST, EAEC adheres to HEp-2 cells in an aggregative adherence (AA) pattern, which is characterized by prominent, 'stacked brick' auto-agglutination of the bacterial cells to each other. EAEC is associated with persistent diarrhoea in the developing world and is also implicated in the developed world as causes of both outbreaks and sporadic diarrhoea among AIDS patients.

STEAEC

Shiga toxin-producing enteraggregative *E. coli* (STEAEC) is an EAEC strain (O104:H4) that has acquired typical EHEC phenotypes, most notably Stx production. STEAEC O104:H4 is responsible for a high percentage of patients developing hemolytic uremic syndrome (HUS) and a mortality rate of 1%. The high morbidity and mortality associated with this strain may reflect the stronger adherence of EAEC compared with EHEC allowing more Stx to be transferred and more resultant pathology.

EIEC

Enteroinvasive *E. coli* (EIEC), which is biochemically, genetically and pathogenetically closely related to *Shigella* spp., induces an invasive inflammatory colitis with a watery diarrhoea syndrome indistinguishable from that caused by other *E. coli* pathotypes and *Shigella* spp. In severe cases, scanty dysenteric stools may contain blood and mucus. Fever and severe cramps may be also present. Like *Shigella*, it may invade intestinal epithelium, principally in the large intestine.

DAEC

Diffusely adherent *E. coli* (DAEC) cause a watery diarrhoea in adults and children that can become persistent. The relative risk of diarrhoea associated with DAEC increases with age of children from 18 months to 5 years. DAEC are differentiated from other diarrhoeic *E. coli* by generating a distinct adhesion phenotype on HEp-2 cells.

AIEC

Adherent-invasive *E. coli* (AIEC) has the capacity to colonize the intestinal mucosa by adhering to intestinal epithelial cells, invade intestinal epithelial cells and replicate in macrophages, contributing to the development of Crohn's disease (CD). The symptoms may range from fever, fatigue, abdominal pain, cramping, nausea, vomiting, bloody stool, mouth sores, reduced appetite, weight loss, perianal disease, to diarrhoea.

UPEC

Uropathogenic *E. coli* (UPEC) is the primary cause of urinary tract infections, including both cystitis and pyelonephritis. This pathotype has evolved a multitude of virulence factors and strategies to facilitate its growth and persistence within the adverse settings of the host urinary tract.

Pathogenesis

EPEC

EPEC produces a heterogeneous group of pertinacious surface structures known as colonization factors (Cuffs), colonization factor antigen I (CFA/I), or coli surface (CS) antigen to facilitate its adhesion and colonization to small-bowel enterocytes. The Cuffs can be fibril, non-fibril or febrile, and to date at least 23 Cuffs have been identified. EPEC febrile confer the species-specificity of the pathogen.

Following the initial adhesion and colonisation in the terminal small intestine, EPEC strains elaborate the heat-labile (LT) and/or heat-stable (ST) enterotoxins that induce diarrhoea. EPEC strains may express an LT only, an ST only, or both.

The heat-labile enterotoxins (LTs) produced by EPEC are an oligomeric class of toxins closely related in structure and function to the cholera enterotoxin (CT) expressed by *Vibrio cholerae*. The LT from human isolates (called LT-I) is ~75% identical at the amino

acid level with CT and shares several phenotypes, including its primary receptor, and mechanism of action. Found primarily in animal *E. coli* isolates and rarely in human isolates, the LT-II toxin has not been associated with disease.

LT-I (or LT) is an oligomeric toxin of ~86 kDa composed of one 28 kDa A subunit and five identical 11.5 kDa B subunits. The B subunits are arranged in a ring or 'doughnut' and bind strongly to the ganglioside GM₁ and weakly to GD_{1b}, and some intestinal glycoproteins. Two closely related variants of LT-I have been described, called LTP for porcine and LTh for human, which exhibit partial antigenic cross-reactivity. The A subunit is responsible for the enzymatic activity of the toxin and is cleaved by proteolysis to yield A₁ and A₂ peptides joined by a disulphide bond. The A₁ domain constitutes the active toxin and the A₂ fragment is the helical portion of the molecule and anchors the A subunit to the B pentamer which binds irreversibly to GM₁ ganglioside as receptors on cell surface.

Both toxins act by changing the net fluid transport activity in the gut from absorption to secretion. LT is structurally similar to cholera toxin and activates the adenylate cyclase–cyclic adenosine monophosphate system, whereas ST works on guanylate cyclase. The intestinal mucosa is not visibly damaged, the watery stool does not contain white or red blood cells, and no inflammatory process occurs in the gut wall. Gut cells activated by LT or cholera toxin remain in that state until they die, whereas the effects of ST on guanylate cyclase are turned off when the toxin is washed away from the cell.

Genes that encode LT, called *elt* or *etx*, reside on plasmids, which may also contain genes encoding ST or CFAs. The genes are arranged as an A-B cluster in which the B ribosomal binding site and the A coding region overlap. The A and B subunits are synthesised individually and secreted through the inner membrane coupled with processing of their typical signal sequences. In the periplasm, the subunits assemble into the mature A₁B₅ configuration, which is held together by non-covalent bonds. The last four residues of the A subunit are required for stability of the holotoxin structure.

After the LT holotoxin binds to the host cell membranes, it is endocytosed and translocated through the cell in a process involving trans-Golgi retrograde transport. Through a series of subsequent steps, the major chloride channel, CFTR, of epithelial cells is activated. This leads to increased secretion of chloride ions by secretory crypt cells. In addition, LT serves to inhibit absorption of sodium chloride by villus tip cells. One additional mechanism by which these toxins may act involves prostaglandins of the E series (PGE₁ and PGE₂) and platelet-activating factor (PAF). Another alternative mechanism involves the enteric nervous system (ENS), which regulates intestinal motility and ion secretion. Serotonin (5-HT) and vasoactive intestinal peptide (VIP), both of which can stimulate intestinal epithelial cell secretion via the ENS, are released into the human small bowel after treatment with CT. A third potential mechanism could involve a mild intestinal inflammatory response due to CT and LT.

The heat-stable enterotoxins (STs) of ETEC are small, monomeric toxins that contain several cysteine residues whose disulphide bonds account for their heat stability. ST is a 71 or 72-amino acid preprotoxin which is processed into an 18–19 amino acid active toxin called STa and a 42 amino acid toxin called STb. STa is produced by both human and animal strains, whereas STb is mainly detected in strains of animal origins.

Genes for both STa and STb classes are predominantly found on plasmids and some ST-encoding genes have been found on transposons. STa (also referred to as ST-I) toxins are produced by ETEC and several other Gram-negative bacteria, including *Yersinia enterocolitica* and *V. cholerae* non-O1.

STa is synthesised as a 72 amino acid precursor ('pre-pro form') that is cleaved by signal peptidase 1 to a 53 amino acid peptide. The disulphide bonds are formed in this 53 amino acid 'pro-form' in the periplasm by the DsbA protein. An undefined periplasmic protease then processes pro-STa to the final 18- or 19-residue mature toxin with a molecular mass of ~2 kDa, which is released by diffusion across the outer membrane.

Two STa variants are known, designated STp (porcine) or STh (human). Both of these can be found in human ETEC isolates and are presumed to be equally pathogenic. STh and STp are nearly identical in the 13 residues necessary and sufficient for enterotoxic activity; of these 13 residues, 6 are cysteines which form three intramolecular disulphide bridges.

The major receptor for STa is a membrane-spanning guanylate cyclase (GC-C). This belongs to a family of receptor cyclases that includes the atrial natriuretic peptide receptors GC-A and GC-B. Binding of STa to GC-C stimulates guanylate cyclase activity, leading to increased intracellular cyclic GMP levels, which in turn produces stimulation of chloride secretion and inhibition of sodium chloride absorption. Ultimately, STa is believed to stimulate the CFTR chloride channel, as does LT. The mechanism of activation by ST is apparently different, however, and may involve cGMP-dependent kinases instead of or in addition to a kinase. The secretory response to STa may also involve phosphatidylinositol and diacylglycerol release, activation of protein kinase C, elevation of intracellular calcium, and microfilament (F-actin) rearrangement.

STb is synthesised as a 71 amino acid precursor protein, which is processed to a mature 48 amino acid protein with a molecular weight of 5.1 kDa. Unlike STa, STb induces histological damage to the intestinal epithelium, which consists of loss of villus epithelial cells and partial villus atrophy. STb also stimulates the release of PGE₂ and serotonin, suggesting that the ENS may also be involved in the secretory response to this toxin.

Apart from CF, two other proteins, the outer membrane protein Tia and the glycosylated autotransporter TibA, are shown to mediate intimate cell attachment and to induce ETEC invasion into epithelial cells. While ETEC binds to leaf surfaces through the flagellum shaft, a novel adhesin, EtpA, located on the tip of ETEC flagella mediates attachment to mammalian host cells. EtpA is degraded by the serine protease autotransporter of Enterobacteriaceae (SPATE), EatA, thereby modulating bacterial adhesion and accelerating delivery of heat labile (LT) toxin into host cells. It is thought that the long-range flagella-EtpA first anchors the bacterium to the host cell and allows shorter CFs to interact. EatA then degrades EtpA and finally intimate attachment is mediated by Tia and TibB.

EPEC

Enteropathogenic *E. coli* (EPEC) strains cause watery and sometimes bloody diarrhoea after the colonization of the mid-distal small intestine (ileum). They recognize their preferred hosts and tissues by means of plasmid-encoded surface adhesins specific for receptors on the intestinal brush-border membranes, called the bundle-forming pili (or fimbriae). Characteristic of EPEC infection is an attachment–effacement (A/E) lesion on the surface of enteric epithelial cells. The affected cells form a broad flat pedestal (effacement) beneath the attached microorganism, which, by damaging the absorptive surface (villi), contributes to the diarrhoea. The genes required for the formation of A/E lesions are located on a 35-kb pathogenicity island called the locus of enterocyte effacement (LEE). Once bound to the epithelial cells, EPEC export critical virulence factors by a type III secretion apparatus, causing several host signals to be activated.

The distinctive histopathology induced by EPEC is the attaching and effacing (A/E) lesion, which results from the intimate attachment of bacteria to the intestinal epithelial cells and subsequent effacement of enterocyte microvilli. Structurally, marked cytoskeletal changes are seen directly beneath the adherent bacteria, which sometimes sit on a pedestal-like structure, with the accumulation of polymerised actin, which can be stained using fluorescein isothiocyanate (FITC)-labeled phalloidin (so called fluorescent actin staining or the FAS test).

The pathogenesis of EPEC infection involves three steps: (i) localised adherence; (ii) signal transduction; and (iii) intimate adherence.

EPEC typically possesses a plasmid which encodes a fimbrial antigen with the ability to aggregate and form bundles (so called 'bundle-forming pilus' or BFP). Production of BFP protein induces the localized adherence (LA) pattern. Most EPEC carry a highly conserved IncF adherence plasmid (i.e., pEAF), and adherence requires at least two large and highly conserved plasmid regions. A 1-kb fragment from one of these regions has been shown to be a useful diagnostic DNA probe (the EAF probe). The N-terminal sequence of the purified fimbriae demonstrates similarity to the TCP pilus of *V. cholerae* and other members of the type IV fimbrial family. A cluster of 13 genes including *per* (encoding plasmid-encoded regulator, Per or BfpTWV) on the EAF plasmid is required for the expression and assembly of BFP. Further, the chromosomal *dsbA* gene encoding a periplasmic enzyme is also required to mediate disulphide bond formation.

After colonisation of the small bowel via BFP, EPEC initiate a more complex cascade of events leading to the A/E lesion and secretory diarrhoea. Adherence of EPEC to epithelial cells activates a variety of signal transduction pathways in the eukaryotic cell. The bacterial genes responsible for this signal transduction activity are encoded on a 35 kb pathogenicity island called the locus of enterocyte effacement (LEE), which encodes a type III secretion system, multiple secreted effector proteins, and outer membrane protein intimin. Mutation of the genes (*espA*, *espB* and *espD*) encoding the secreted proteins or the gene (*sep*) encoding the type III secretion system abolishes these multiple signaling events. The product of the *espA* gene forms a short pilus-like structure that serves both as an adhesin in the early stages of EPEC pathogenesis and as a conduit through which the other Esp proteins pass on their way to the eukaryotic cell cytoplasm.

The binding of EPEC to cultured epithelial cells triggers the release of inositol phosphates including IP₃, and IP₄ in infected cells, which results in release of calcium from intracellular stores. The increase in inositol phosphates is due probably to activation of phospholipase C in the host cell. Buffering of intracellular calcium greatly reduces the polymerisation of actin and formation of the A/E lesion. Moreover, increases in intracellular calcium can inhibit absorption of sodium and chloride ions, and stimulate chloride secretion in enterocytes. In addition, adherence of EPEC to epithelial cells results in phosphorylation of several epithelial cell proteins on serine and threonine residues, the most prominent of which is myosin light chain (MLC). Activation of protein kinase C (PKC) induces rapid changes in intestinal water and electrolyte secretion and phosphorylation of MLC together contributes to increased permeability of tight junctions.

Binding of EPEC to HeLa cells also induces protein phosphorylation on tyrosine residues. The major tyrosine-phosphorylated protein is a 90-kDa epithelial cell membrane protein called Hp90. The tyrosine-phosphorylated proteins are part of the A/E lesion and the distribution of the phosphorylated proteins is restricted to an area immediately beneath the adherent bacteria at the tip of the pedestals. The tyrosine phosphorylated Hp90 serves as a receptor for the intimin adhesin. Indeed, the signal transduction induced in epithelial cells by EPEC may induce formation of the mature receptor as well as cause subsequent cytoskeletal re-arrangements.

Intimate adherence of EPEC to epithelial cells is mediated by a 94–97-kDa outer-membrane protein called intimin which is encoded by *eae*, a gene located on the locus of enterocyte effacement (LEE). The *eae* gene is present in all EPEC, EHEC, *Citrobacter rodentium*, and *Hafnia alvei* strains capable of producing the A/E histopathology but is absent from *E. coli* of the normal flora, ETEC and other bacterial species that do not produce the A/E lesion. Intimin is essential for full virulence of EPEC strain E2348/69, but that additional virulence factors are required for disease. Intimin is immunogenic and may be useful as an antigen in EPEC vaccine development.

EHEC

Several EHEC serogroups (e.g., O26:H11, O91:H21, O111:H8, O157:NM, and O157:H7) are associated with EHEC infection in humans. Of these, O157:H7 is the most common in the United States, whereas O26 is found with greater frequency elsewhere in the world. EHEC strains have two special characteristics of pathogenic importance. First, they produce high levels of two related cytotoxins that resemble toxins of *Shigella*, with the same protein synthesis-inhibitory action and binding specificity. These toxins are therefore called Shiga-like toxins (SLT) I and II. The SLT are cytotoxic for endothelial cells in culture. Second, they possess a gene highly homologous to the EPEC attaching and effacing pathogenicity island. In combination, the proteins encoded by this gene and

the SLT presumably damage the gut mucosa in a manner characteristic of hemorrhagic colitis. EHEC strains cause systemic manifestations (hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura in adults) that are believed to be related to systemic absorption of SLT, possibly in combination with endotoxin, which up-regulates the expression of the SLT receptor on host cells. These syndromes represent the clinical response to endothelial damage of glomeruli and the central nervous system. Organ damage is sometimes permanent.

It is evident that O157:H7 may have emerged through four sequential events: (i) acquisition of an *stx2*-containing bacteriophage, (ii) acquisition of pO157 and the *rfb* region, (iii) acquisition of the *stx1*-containing bacteriophage, and (iv) loss of the ability to ferment D-sorbitol and loss of beta-glucuronidase (GUD) activity.

The shiga toxin family contains two major, immunologically non-cross reactive groups of toxins, Stx1 and Stx2. The genes for Stx1 and Stx2 are encoded on lysogenic lambdoid bacteriophage. A single EHEC strain may express either or both toxins, or even multiple forms of Stx2. As Stx2 is more potent in inducing cytotoxicity and more important in the development of HUS than Stx1, O157:H7 strains expressing Stx2 alone are more likely to be associated with progression to HUS than strains producing Stx1 alone or, curiously, both Stx1 and Stx2. Stx1 from EHEC is identical to shiga toxin from *Shigella dysenteriae* I, but for a single amino acid difference. Production of Stx1 by *E. coli* and *S. dysenteriae* is repressed by iron and reduced temperature, but expression of Stx2 is unaffected by these factors.

Structurally, Stx is composed of one enzymatically active A subunit (A1) and five identical receptor-binding B subunits (B5). The prototypic Stx1 and Stx2 toxins respectively share 55 and 57% sequence identity in the A and B subunits. After the B5 subunit binds to the specific host receptors globotriaosylceramide (Gb3) or globotetraosylceramide (Gb4), Stx is endocytosed through coated pits and is transported to the Golgi apparatus and then to the endoplasmic reticulum. The A subunit is translocated to the cytoplasm, where as an *N*-glycosidase it inhibits protein synthesis by the specific removal of a single adenine residue from the 28S rRNA of the 60S ribosomal subunit. The resulting disruption of protein synthesis leads to death of renal endothelial cells, intestinal epithelial cells, Vero or HeLa cells, or any cell which possesses the Gb3 receptor, or for Stx2 the Gb4 receptor [10].

The locus of enterocyte effacement (LEE) pathogenicity island, which confers the A/E phenotype on EPEC, is of 43 kb in *E. coli* O157:H7, which contains an additional 7.5 kb prophage sequence compared with EPEC strains (whose LEE is of 35 kb). The LEE comprises at least 41 different genes organized into three major regions: (i) a type III secretion system (TTSS) that exports effector molecules; (ii) an adhesion called intimin and its translocated receptor, Tir, which is translocated into the host cell membrane by the TTSS; and (iii) several secreted proteins (Esp) as a part of TTSS, which are important in modification of host cell signal transduction during the formation of A/E lesions.

E. coli O157:H7 has a highly conserved nonconjugative F-like plasmid (pO157) with a size of 92–104 kb. The pO157 shows a dynamic structure and includes different mobile genetic elements such as transposons, prophages, insertion sequences (IS), and parts of other plasmids. IS or remnants of IS are frequently associated with the virulence-related segments, which are similar to compositions of the large virulence plasmid in *Shigella* spp. Of the 100 ORFs in pO157, 43 show sufficient similarities to known proteins, including a haemolysin (ehxA), a catalase-peroxidase (katP), a type II secretion system apparatus (etp), a serine protease (espP), a putative adhesin (toxB), a zinc metalloprotease (stcE) and an *eae* conserved fragment (ecf).

The classical intestinal histopathology of haemorrhagic colitis due to *E. coli* O157:H7 includes haemorrhage and oedema in the lamina propria. Biopsies of the colon from many patients also show focal necrosis and neutrophil infiltration. The overall pattern resembles a combination of ischaemic and infection injuries similar to those described in toxin-mediated *Clostridium difficile*-associated colitis, and pseudomembranes are seen in many patients.

Similarly to EPEC, *E. coli* O157:H7 induces a host inflammatory response that is apparently linked to the attaching and effacing (A/E) histopathology. The ability of EHEC to cause the A/E lesions is probably sufficient to cause non-bloody diarrhoea, but shiga toxin (Stx) is essential for the development of bloody diarrhoea and haemorrhagic colitis. Stx induced damage to the microvasculature endothelium is the underlying mechanism of the syndrome.

The typical human renal histopathology includes swollen glomerular endothelial cells and deposition of platelets and fibrin in the glomeruli. Stx is believed to damage the glomerular endothelial cells leading to narrowing of capillary lumina and occlusion of the glomerular microvasculature with platelets and fibrin. The decreased glomerular filtration rate is presumably responsible for the acute renal failure that is typical of HUS. The fragmented erythrocytes characteristic of HUS may be the result of red cell injury caused by passage across the occluded microvasculature.

Although the simplest mechanism for HUS involves a direct cytotoxic action of Stx on renal endothelial cells, several studies also support a role for cytokines in this process. Purified Stx induces the expression of proinflammatory cytokines such as tumour necrosis factor α (TNF α) and interleukin 6 (IL-6) by murine peritoneal macrophages, as well as specific synthesis of TNF α in the kidney. TNF α and IL-1 β can enhance the cytotoxic effect of Stx on human vascular endothelial cells *in vitro* and these two cytokines, as well as TNF β and bacterial LPS, induce expression of globotriaosylceramides (Gb3) and increase binding of Stx to human endothelial cells. In clinical studies, elevated levels of IL-6 are found in serum and urine of HUS patients and the levels of IL-6 correlate with severity and outcome of disease.

EAEC

Infection with EAEC induces cytotoxic effects on the intestinal mucosa. The lesion is characterised by shortening of the villi, haemorrhagic necrosis of the villus tips and a mild inflammatory response with oedema and mononuclear infiltration of the sub-mucosa. The bacteria adhere to enterocytes without formation of the attaching and effacing lesion [12].

The mode of action of EAEC comprises three stages. Stage I involves initial adherence to the intestinal mucosa and/or the mucus layer, and aggregative adherence fimbriae (AAF)/I and /II are the leading candidates for factors which may facilitate initial colonisation. Stage II includes enhanced mucus production, leading to deposition of a thick mucous-containing biofilm encrusted with EAEC. The mucous blanket may promote persistent colonisation and perhaps nutrient malabsorption. Stage III includes the elaboration of an EAEC cytotoxin(s) and enterotoxin which result in mucosal damage and fluid secretion.

Aggregative adherence fimbriae (AAF) are encoded by a 55–65 MDa plasmid named pAA. A transcriptional activator known as 'AggR,' encoded by pAAs, is the major EAEC virulence regulator controlling diverse virulence genes encoded by pAAs (including biogenesis of AAF) as well as by chromosomes. Adherence of EAEC to the mucosa is characterized by the formation of a thick, aggregating mucus layer inside which they survive and this biofilm production has been attributed to the activity of *fis* and *yafK* genes. A secreted protein of 10 kDa encoded by pAA and called antiaggregation protein (Aap) or dispersin, facilitates the movement of bacteria across the surface of the cells for subsequent aggregation and adherence.

EAEC produce a variety of SPATEs of either class I (cytotoxic) or class II (non-cytotoxic). Pic (protease involved in colonization, also found in *Shigella flexneri* and UPEC) is a class II SPATE with haemagglutinin and mucinolytic activity. It may help penetrate the mucus layer in which EAEC resides on enterocytes. Pet is a class I SPATE that is endocytosed by host cells, undergoes retrograde trafficking and utilizes the ER-associated degradation (ERAD) pathway to be released into the cytosol. Pet then cleaves the actin binding protein spectrin in the host cytosol, disrupting the actin cytoskeleton and causing cell rounding and detachment. As Pet is only present in a small minority of strains, alternative class I SPATES (Sat, SigA, EspP) may have similar roles. Sat in particular has 52% amino acid identity with Pet.

In addition, EAEC elaborate an EAEC ST-like toxin (EAST1), which is a non-SPATE toxin showing 50% homology to the enterotoxin domain of STa. EAST1 is a 38 amino acid protein of 4.1 kDa with 4 cysteine residues, unlike the 6 residues characteristic of *E. coli* STa. Similar to STa, EAST-1 activates guanylate cyclase leading to increased cGMP, although the toxigenic effect is milder than for STa. EAST1 is detected in ~40% of EAEC strains, as well as in other *E. coli* categories, notably the EHEC. EAEC also produce cytotoxin, which is a 108 kDa protein with enterotoxin activity. Other toxins include ShET1 (an AB₅ toxin in *Shigella flexneri*) and HlyE (a pore-forming toxin) may also contribute to EAEC virulence.

STEAEC

STEAEC outbreak strain O104:H4 carries Pic on the chromosome and a pAA-like virulence plasmid encoding AAF, AggR, Pet, ShET1 and dispersin. A second virulence plasmid encodes multiple antibiotic resistances. Besides these standard EAEC virulence determinants, STEAEC O104:H4 has a *stx2*-harbouring prophage integrated into the *wrbA* locus, allowing production of Stx, a defining characteristic of the EHEC pathotype. The outbreak strain has also acquired the IrgA homolog adhesin (Iha) and a tellurite resistance cluster, which are common features of EHEC strains. Therefore, STEAEC O104:H4 is a combination of known virulence determinants from two pathotypes.

EIEC

The current model of *Shigella* and EIEC pathogenesis involves: (i) epithelial cell penetration, followed by; (ii) lysis of the endocytic vacuole; (iii) intracellular multiplication; (iv) directional movement through the cytoplasm and (v) extension into adjacent epithelial cells. When severe, this sequence of events elicits a strong inflammatory reaction cluster of secreted effector proteins.

Both EIEC and *Shigella* invade the colonic epithelium, a process that requires specific chromosomal and plasmid-borne virulence genes.

Invasion-related genes are carried on a 120-MDa plasmid (pInV) in *S. sonnei* and a 140-MDa plasmid in other *Shigella* serotypes and in EIEC. Acquisition of the invasive plasmid (pInV) encoding the ability to invade host tissues has contributed to the evolution of both *Shigella* and EIEC from non-pathogenic *E. coli*. The *mxi* and *spa* gene clusters, which encode a plasmid-borne type III secretion system (T3SS), are required for the secretion of multiple virulence. The movement of *Shigella* and EIEC in the cytoplasm is mediated by nucleation of cellular actin into a 'tail' which extends from one pole of the bacterium. As additional actin is added to this structure, the bacterium is propelled through the cytoplasm, generally in a lateral direction. A surface protein, VirG (IcsA), is essential for the nucleation of actin filaments and movement through the cytoplasm and into adjacent cells. In addition, many chromosomal genes (e.g., *virR* which encodes a histone-like protein) are carried on the chromosome with key roles in pathogenesis. VirR apparently acts in concert with VirF, a transcriptional activator encoded on pInV. VirF exerts pleiotropic effects, some of which are through the intermediate transcriptional activator VirB. EIEC strains may also produce a 63 kDa toxin designated Sen with enterotoxin activity, and mutation of the *sen* gene causes a significant diminution of the enterotoxin activity of the parent strain.

Interestingly, of the three T3SS-dependent pathotypes, EHEC and EPEC primarily remain extracellular during infection while EIEC are found intracellular. Despite these very different lifestyles and the different T3SS origins (LEE encoded or pINV encoded, respectively) EPEC/EHEC and EIEC/*Shigella* actually share a number of T3SS translocated proteins, e.g., EspG/VirA, EspO/OspE, NleE/OspZ reflecting similar infection strategies.

DAEC

The typical class of DAEC includes *E. coli* strains that harbour AfaE-I, AfaE-II, AfaE-III, AfaE-V, Dr, Dr-II, F1845, and NFA-I adhesins (Afa/Dr DAEC); these strains (i) have an identical genetic organization and (ii) allow binding to human decay-accelerating factor

(DAF) (Afa/Dr(DAF) subclass) or carcinoembryonic antigen (CEA) (Afa/Dr(CEA) subclass). The atypical class of DAEC includes two subclasses of strains; the atypical subclass 1 includes *E. coli* strains that express AfaE-VII, AfaE-VIII, AAF-I, AAF-II, and AAF-III adhesins, which (i) have an identical genetic organization and (ii) do not bind to human DAF; and the atypical subclass 2 includes *E. coli* strains that harbour Afa/Dr adhesins or others adhesins promoting diffuse adhesion, together with pathogenicity islands such as the LEE pathogenicity island.

The diffusely adherent phenotype of DAEC on HEp2 cells is due largely to the action of afimbrial (Afa) or fimbrial (Dr) adhesins (Afa-Dr adhesins). While all Afa/Dr adhesins bind the DAF, a subfamily of Afa/Dr adhesins (AfaE-III, Dr and F1845 adhesins) also bind carcinoembryonic antigen-related molecules (CEACAMs) and the Dr adhesin also bind type IV collagen. A small number of DAEC strains may also express the CS20 colonization factor from ETEC.

After the Afa/Dr adhesins bind their cellular target on enterocytes (DAF or CEACAMs) they relocate the target around the site of bacterial attachment. For the Dr adhesin this relocation is dependent on Src kinase activation. Following target mobilization, enterocyte signaling pathways (e.g., MAPK and PI3K) are activated and IL-8 is synthesized (for the F1845 adhesin this requires HIF-1 α) inducing transepithelial migration of human polymorphonuclear neutrophils (PMN). This stimulates the enterocytes to synthesize TNF α and IL-1 β and upregulate DAF to strengthen bacterial adhesion. DAEC can interact with the transmigrating PMNs and induce type I pili-dependent IL-8 release. Transmigrated PMNs are also induced to undergo apoptosis after interaction with DAEC and have a diminished phagocytic capacity, prolonging bacterial persistence in the gut.

The secreted factor associated with DAEC infection is the SPATE Sat, which can induce rearrangement of the tight junction proteins ZO-1, ZO-3 and occludin increasing paracellular permeability but not transepithelial resistance and can also bind spectrin, rearrange focal adhesion associated proteins vinculin and paxillin, and cause cell detachment and caspase-independent cell death.

AIEC

AIEC has the ability to (i) adhere to and invade intestinal epithelial cells, and (ii) survive and replicate expansively within macrophages without triggering host cell death and inducing the release of tumor necrosis factor alpha. AIEC strains are clonally diverse and belong to distinct serotypes. AIEC strains carry many virulence-associated genes characteristic of extraintestinal pathogenic *E. coli* (ExPEC) strains.

UPEC

UPEC typically expresses an array of fimbrial and afimbrial adhesins, secreted toxins, haemolysin, iron acquisition systems, capsular polysaccharide etc. to facilitate entry and survival in urinary tract. Specifically, UPEC utilises type 1 and P pili to bind and invade host cells and tissues within the urinary tract, and employs iron-chelating factors (siderophores) to pilfer host iron stores. In addition, UPEC makes use of an array of toxins, such as haemolysin and cytotoxic necrotizing factor 1, to inflict extensive tissue damage, which contributes to bacterial dissemination, releasing host nutrients and disabling immune effector cells. However, unlike many diarrheogenic *E. coli* isolates, UPEC lacks the type III secretion system to inject VFs into target host cells.

Diagnosis

E. coli is a Gram-negative, non-spore forming, facultative anaerobic, rod-shaped bacterium of about $0.6 \times 2 \mu\text{m}$ in size. On EMB agar, the bacterium often forms non-spreading colonies with a characteristic green sheen.

Biochemically, *E. coli* is capable of reducing nitrates to nitrites and producing lactate, succinate, ethanol, acetate and carbon dioxide. Most *E. coli* strains are positive for catalase, but negative for oxidase, citrate, urease and hydrogen sulfide. In addition, it is positive for indol production and the methyl red test. *E. coli* can be discriminated from the closely related *Shigella* and *Salmonella* by its ability to ferment lactose. For this reason, lactose is included as the sole added sugar together with a pH indicator in agar media. Lactose fermenting colonies (presumptively those of *E. coli*) turn a distinctive color due to the production of acid. Nevertheless, it should be noted that only about 90% of *E. coli* are lactose-positive. The indol test, positive in about 98% of *E. coli*, is a better test for biochemical differentiation from other Enterobacteriaceae. EHEC strains of the serotype O157:H7 are nearly unique in their inability to ferment sorbitol. Nonfermenting colonies are detected on sorbitol containing MacConkey agar and confirmed with a sensitive and specific latex agglutination test.

A more specific approach to define *E. coli* strains and pathotypes is through examination of their antigenic compositions, such as O (lipopolysaccharide), H (flagellar), K (capsular), and F (fimbrial) antigens (proteins), and their phage and colicin sensitivity. This is assisted with the use of polyclonal or monoclonal antibodies in various serological procedures, ranging from mannose-resistant agglutination of erythrocytes, enzyme-linked immunosorbent assay (ELISA), passive latex agglutination, to immunoprecipitation in agar and Biken test.

Use of cultured cells such as epithelial HEp-2 and HeLa cells provides a valuable means to characterise *E. coli* pathotypes. Indeed, HEp-2 cell-adherence assay allows differentiation among EPEC, EAEC, and DAEC isolates, while HeLa cell monolayers provide a reliable method to detect plaque-forming EIEC isolates. Given that LT produces morphological changes on Y1 adrenal and Chinese hamster ovarian cell lines that are neutralizable by antitoxin, tissue culture tests may be employed in preference to the rabbit ileal loop for LT detection. In addition, infant mouse physiological assay may be applied for ST identification, and guinea pig may be useful to detect keratoconjunctivitis caused by EIEC isolates.

The availability of detailed knowledge of the *E. coli* genetic structures enabled the development of rapid, sensitive and specific laboratory techniques for identification and typing of *E. coli* strains and pathotypes. Molecular and fluorogenic typing methods useful for diagnostic purposes have been developed to detect toxins, pili, and other virulence factors. For example, PCR procedures are useful for detection of *pap*, *afa*, and *sfa* genes in UIPEC. In addition, multiplex PCR and real time PCR permit simultaneous detection of one or more diarrhoeagenic *E. coli* pathotypes.

Glossary

Adaptation A feature of an organism that enhances its reproductive success and that evolved by natural selection.

Epistasis An interaction among genes, such that the effect of a mutation depends on the genetic background in which it occurs.

Evolution Change in the genetic properties of populations and species over generations, which requires the origin of variation (by mutation or mixis) as well as the subsequent spread or extinction of variants (by natural selection and genetic drift).

Fitness Average reproductive success of a genotype in a particular environment, usually expressed relative to another, standard genotype.

Genetic drift Changes in gene frequency caused by the random sampling of genes during transmission across generations (rather than by natural selection).

Mixis Production of a new genotype by recombination of genes from two sources.

Natural selection Changes in gene frequency caused by specific detrimental or beneficial effects of those genes.

Population Group of individuals belonging to the same species and living in close proximity, so that individuals may potentially recombine their genes, compete for limiting resources, or otherwise interact.

Abbreviations

GASP Growth Advantage in Stationary Phase

MOI Multiplicity of infection

Defining Statement

Evolution in action can be studied by experiments in the laboratory using bacteria and other microorganisms with suitably rapid generation. These experiments have confirmed the main principles of modern evolutionary theory, while also providing new insights into the genetics, physiology, and ecology of microorganisms.

Review of Evolutionary Theory

Evolutionary theory seeks to explain observable patterns of biological diversity in terms of a few fundamental evolutionary processes. These processes are presumed not only to have operated in the past, but also to continue to operate today. Thus, they can be studied experimentally in the laboratory. Before discussing a broad range of experiments that have used microorganisms to examine evolutionary processes, the major elements of evolutionary theory will be reviewed.

Evolutionary Patterns

The three most conspicuous products of organic evolution are (1) the wealth of genetic variation that exists within almost every species; (2) the divergence of populations and species from one another and from their common ancestors; and (3) the manifest adaptation, or fit, of organisms to the environments in which they live.

Genetic variation

The existence of extensive genetic variation within species has been demonstrated by a variety of means. Variation in certain traits, such as seed shape in pea plants and blood type in humans, can be shown to have a genetic basis by careful examination of pedigrees. For many other traits, such as milk production in cows or body weight in humans, quantitative genetic analyses are required to partition the phenotypic variation that is due to genetic versus environmental influences. Biochemical and molecular techniques have also revealed extensive variation in DNA sequences and the proteins they encode.

[☆]*Change History:* August 2016. M.J. Wiser and R.E. Lenski updated Sections "Glossary," "Genetic and Physiological Bases of Fitness," "Evolution of New Metabolic Functions," and "Evolution of New Genetic Systems."

This article is an update of R.E. Lenski, M.J. Wiser, Evolution, Theory and Experiments With Microorganisms, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 550–564.

Divergence and speciation

All biological species differ from one another in some respects. It is generally possible to arrange species hierarchically, depending on the extent and nature of their similarities and differences. This hierarchy is reflected in the classification scheme of Linnaeus (species, genus, family, and so on). This hierarchical arrangement also suggests a sort of “tree of life” in which the degree of taxonomic relatedness between any two species reflects descent with modification from some common ancestor in the more or less distant past. Investigating the origins of groups and their relationships requires an historical approach, which is not amenable to direct experimentation. Even so, historically based hypotheses can be tested by phylogenetic and comparative methods, which utilize data on the distribution of traits across various groups and environments, sometimes supplemented with information from the fossil record.

The extent of evolutionary divergence that is necessary for two groups of organisms to be regarded as distinct species is embodied in the biological species concept, according to which “species are groups of actually or potentially interbreeding populations, which are reproductively isolated from other such groups” (E. Mayr, in 1942). Speciation thus refers to the historical process by which groups of organisms become so different from one another that they no longer can interbreed. However, many organisms (including most microorganisms) reproduce primarily or exclusively asexually, and the preceding definition is not applicable. For such organisms, the extent of evolutionary divergence that corresponds to distinct species is somewhat arbitrary and often more a matter of convenience than of scientific principle.

Adaptation

Many phenotypic features of organisms often exhibit an exquisite match to their environments. For example, the bacteria that live in hot springs have special physiological and biochemical properties that allow them to survive and grow at very high temperatures, which would kill most other bacteria; often these thermophiles cannot grow at all under the lower temperatures where most other bacteria thrive. However, organisms are also generally not perfectly adapted to their environments. Evidence for the imperfection of organisms can be seen when species go extinct, usually as a consequence of some change in the environment to which they cannot quickly adapt.

Evolutionary Processes

Biological evolution occurs whenever the genetic composition of a population or species changes over a period of generations. Four basic processes contribute to such change: mutation, mixis, natural selection, and genetic drift. Selection and drift will not produce evolutionary changes, however, unless there exists genetic variation among individual organisms.

Sources of genetic variation

Genetic variation among individuals is generated by two distinct processes, mutation and mixis. In terms of evolutionary theory, these processes are usually distinguished as follows: mutation refers to a change at a single gene locus from one allelic state to another (eg, $abcd \rightarrow Abcd$, where each letter indicates a locus), whereas mixis refers to the production of some new multilocus genotype by the recombination of two different genotypes (eg, $abcd + BCD \rightarrow aBcD$).

There are many different types of mutations, including point mutations, rearrangements, and transposition of mobile elements from one site in the genome to another. Some mutations cause major changes in an organism’s phenotype; for example, a bacterium may become resistant to attack by a virus (bacteriophage) as a result of a mutation that alters a receptor on the cell surface. Other mutations have little or even no effect on an organism’s phenotype: many point mutations have absolutely no effect on amino acid sequence (and hence protein structure and function) because of the redundancy in the genetic code.

Any number of factors may affect mutation rates, including both environmental agents (eg, UV irradiation) and the organism’s own genetic constitution (eg, defective DNA repair genes). Evolutionary theory makes no assumptions about the rates of mutations or their biophysical bases, with one exception: mutations are assumed to occur randomly, that is, irrespective of their beneficial or harmful effects on the organism.

Recombination among genomes can occur by a number of different mechanisms. The most familiar one is eukaryotic sex, which occurs by meiosis and fertilization. Many eukaryotic microorganisms, including fungi and protozoa, engage in sexual mixis. Bacteria generally reproduce asexually, but may undergo mixis via conjugation (plasmid-mediated), transduction (virus-mediated), or transformation. Even viruses may recombine when two or more coinfect a single cell.

Unlike mutation, these various mechanisms do not necessarily produce organisms with new genes; instead, they may produce organisms that possess new combinations of genes. This can have very important evolutionary consequences. In the absence of mixis, two or more beneficial mutations can be incorporated into an evolving population only if they occur sequentially in a single lineage. Mixis allows beneficial mutations that occur in separate lineages to be combined and thereby incorporated simultaneously by an evolving population. Thus, mixis may accelerate the rate of adaptive evolution by bringing together favorable combinations of alleles.

Natural selection

One of the most conspicuous features of biological evolution is the evident “fit” (adaptation) of organisms to the environments in which they live. For centuries, this match between organism and environment was taken as evidence for the design of a Creator. But in 1859, Charles Darwin published *“The Origin of Species”*, in which he set forth the principle of adaptation by natural selection.

This principle follows logically from three simple premises. First, variation among individuals exists for many phenotypic traits. Second, these phenotypic traits influence survival and reproductive success. Third, phenotypic variation in those characters that affect survival and reproductive success is heritable, at least in part. (Many phenotypic traits are subject to both genetic and environmental influences.) Hence, individuals in later generations will tend to be better adapted to their environment than were individuals in earlier generations, provided that there is heritable phenotypic variation and the environment has not changed too much in the intervening time. (Environments do sometimes change, of course, and when this happens a population or species may go extinct if it cannot adapt to these changes.)

Darwin himself did not know about the material basis of heredity (DNA and chromosomes), nor did he even understand the precise causes of heritable variation among individuals (mutation and mixis). What he clearly understood, however, was that this heritable variation did exist and its causes could be logically separated from its consequences for the reproductive success of individuals and the resulting adaptation of species to their environments.

Darwin's theories were influenced, in part, by his observations on the practices of breeders of domesticated animals and plants. These practices are now commonly referred to as artificial selection. It is useful to distinguish between artificial and natural selection, and to relate this distinction to experimental evolution in the laboratory. Under artificial selection, organisms are chosen by a breeder, who allows some but not all individuals to survive and reproduce. Individuals are thus selected on the basis of particular traits that are deemed desirable to the breeder. By contrast, under natural selection, no one consciously chooses which individuals within a population will survive and reproduce and which will not. Instead, the match between organismal traits and environmental factors determines whether or not any given individual will survive and reproduce.

At first glance, one might regard laboratory studies as examples of artificial selection. Such usage, however, would not reflect the critical distinction between artificial and natural selection, that is, whether a breeder or the environment determines which individuals survive and reproduce. In experimental evolution, an investigator typically manipulates environmental factors, such as temperature and resource concentration, but he or she does not directly choose which individuals within an experimental population will survive and reproduce. Instead, natural selection in the laboratory, like natural selection in the wild, depends on the match between organismal traits and environmental factors.

Genetic drift

The frequency of genes within populations, and hence also the distribution of phenotypic traits, may change not only as a consequence of natural selection, but also as a consequence of the random sampling of genes during transmission across generations. This random sampling is called genetic drift. In practice, it can be difficult to distinguish between natural selection and genetic drift, although statistical methods have been developed that may allow one to distinguish between these forces by comparing DNA sequences among related strains. Alternatively, by using microorganisms to study evolution experimentally, it is possible to compare the survival and reproductive success of different genotypes that are placed in direct competition with one another. With proper replication of such experiments, one can distinguish systematic differences in survival and reproductive success from chance deviations due to drift.

Experimental Tests of Fundamental Principles

Two key principles of evolutionary theory are the randomness of mutation and adaptation by natural selection. According to the former, mutations occur irrespective of any beneficial or harmful effects they have on the individual organism. According to the latter, organisms in later generations tend to be better adapted to their environment than were those in earlier generations, provided that the necessary genetic variation exists and the environment itself does not change.

Random Mutation

For many years, it was known that bacteria could adapt to various environmental challenges. For example, the introduction of bacteriophage into a population of susceptible bacteria often caused the bacterial population to become resistant to viral infection. It was unclear, however, whether mutations responsible for bacterial adaptation were caused directly by exposure to the selective agent, or whether this adaptation was the result of random mutation and subsequent natural selection. Two elegant experiments were performed in the 1940s and 1950s, which demonstrated that mutations existed prior to exposure to the selective agent, so that these mutations could not logically have been caused by that exposure.

Fluctuation test

The first of these experiments was published by Salvador Luria and Max Delbrück in 1943, and it relies on subtle mathematical reasoning. Imagine a set of bacterial populations, each of which grows from a single cell to some large number of cells (N); the founding cells are identical in all of the populations. If exposure to the selective agent causes a bacterial cell to mutate with some low probability (p), then the number of mutants in a population is expected to be, on average, pN . Although this probability is the same for each of the replicate populations, the exact number of mutants in each population may vary somewhat due to chance (just as the number of heads and tails in 20 flips of a fair coin will not always equal exactly 10). Mathematical theory shows that the expected

variance in the number of mutants among the set of replicate populations is equal to the average number of mutants under this hypothesis.

Now imagine this same set of populations, but assume that mutations occur randomly, that is, independent of exposure to the selective agent. During each cell generation, there is a certain probability that one of the daughter cells is a mutant. A mutant cell's progeny are also mutants, and so on. According to mathematical theory for this hypothesis, the variance in the number of mutants among the replicate populations should be much greater than the average number of mutants. This large variance comes about because mutations will, by chance, occur earlier in some replicate populations than in others, and each of the early mutations will leave many descendant mutants as a consequence of the subsequent population growth.

Luria and Delbrück designed experiments that allowed them to measure both the average and the variance of the number of mutants in a set of populations of the bacterium *Escherichia coli*. The observed variance was much greater than expected if exposure to the selective agent had caused the mutations. Hence, their results supported the hypothesis of random mutation.

Replica-plating experiment

Joshua and Esther Lederberg devised a more direct demonstration of the random origin of bacterial mutations, which they published in 1952. In their experiment, thousands of cells are spread on an agar plate that does not contain the selective agent; each cell grows until it makes a small colony, and the many colonies together form a lawn of bacteria (master plate). By making an impression of this plate using a pad of velvet, cells from all of the colonies are then transferred to several other agar plates (replica plates) that contain the selective agent, which prevents the growth of colonies except from those cells with the appropriate mutation. If mutations are caused by exposure to the selective agent, then there should be no tendency for mutant colonies found on the replica plates to be derived from the same subset of colonies on the master plate. However, if mutations occur during the growth of the colony on the master plate (ie, prior to exposure to the selective agent), then those master colonies that give rise to mutant colonies on one replica plate should also give rise to mutant colonies on the other replica plates. Indeed, Lederberg and Lederberg observed that master colonies giving rise to mutants on one replica plate gave rise to mutants on the other replica plates. Moreover, they could isolate resistant mutants from those master colonies, without the cells having ever been exposed to the selective agent. This experiment thus demonstrates that the mutations had occurred randomly during the growth of the colony on the master plate.

Adaptation by Natural Selection

In addition to demonstrating the random occurrence of mutations, the fluctuation test and the replica plating experiment both demonstrate adaptation by natural selection. Two other types of experiments also demonstrate adaptation by natural selection. One type is very complicated and involves monitoring the dynamics of mutation accumulation at one genetic locus, which is not under selection, in order to study indirectly what is happening at some other loci, which are under selection.

The other type of experiment that demonstrates adaptation by natural selection involves direct estimation of an evolving population's fitness relative to its ancestor, and it is conceptually quite simple. A population is founded by an ancestral clone, which is also stored in a dormant state (usually at very low temperature). The population is then propagated in a particular environment, and one or more samples are obtained after many generations have elapsed. These derived organisms are placed in direct competition with the ancestral clone under the same defined environmental conditions (after both types have acclimated physiologically to these conditions). If the derived organisms increase their number relative to the ancestral clone, in a systematic and reproducible fashion, then the evolving population has evidently become better adapted to the environment as the result of mutation and natural selection.

To distinguish the derived and ancestral types from one another in a competition experiment, it is usually necessary to introduce a genetic marker that can be scored into one of them. This genetic manipulation necessitates an appropriate control experiment to estimate the effect of the genetic marker on fitness.

Genetic and Physiological Bases of Fitness

The fact that one strain may be more fit than another in a particular environment usually says little or nothing about the causes of that difference. It is interesting to know why one strain is more fit than another in terms of their genotypes and their physiological properties. By using both classical and molecular genetic methods, one can construct genotypes of interest and then determine the effects of their differences on physiological performance and fitness.

Effects of Single and Multiple Mutations

A study by Santiago Elena and Richard Lenski examined systematically the fitness effects of a large set of random mutations. Using transposon mutagenesis, they made 225 genotypes of *E. coli* that each carried one, two, or three insertion mutations. Each genotype was then placed in competition with the unmutated progenitor strain in order to measure the fitness of the mutant relative to the progenitor. Single insertion mutations reduced fitness by about 2%, on average, and there was tremendous variability in the

mutational effects, which ranged from approximately neutral to effectively lethal under the conditions where the competitions were performed. The relationship between average fitness and mutation number was approximately log-linear. That is, subsequent mutations were neither more nor less harmful, on average, than was the first mutation. However, many pairs of mutations interacted strongly with one another, so that their combined effect on fitness was different from what was expected given their separate effects. (The overall relationship between average fitness and mutation number was approximately log-linear because some interactions were synergistic whereas others were antagonistic.) These data imply that a full understanding of the genetic basis of any organism's functional capacity cannot depend entirely on the step-by-step analysis of individual genes and pathways; instead, a more integrative approach is necessary.

Another approach is to investigate both the actual and possible alternative evolutionary paths that lead from an ancestor to a derived state that has accumulated multiple mutations. A study by Daniel Weinreich and colleagues examined a set of five point mutations in *E. coli* that, in combination, increase resistance to the β -lactam cefotaxime by a factor of $\sim 100,000$. With five mutations, there are 120 possible paths to obtain the full complement sequentially, but only 18 of them result in strictly increasing levels of resistance to this antibiotic. The large fraction of mutational paths along which antibiotic resistance either decreased or remained the same across one or more steps indicates pervasive epistasis in this system. In contrast, a study by Aisha Khan and colleagues examined the first five mutations that arose in a population of *E. coli* as it evolved in a nutrient-limited environment; the combination of these mutations increased fitness by $\sim 30\%$ relative to the ancestor. In this study, 86 of the 120 paths from the ancestor to the genotype with all five mutations were monotonically increasing in fitness, indicating that epistasis was not a substantial barrier to adaptation. Which of these two situations is more typical remains an open question in the field.

The study by Khan *et al.* also provided evidence of diminishing returns as populations adapt to a constant environment. That is, when they moved beneficial mutations into different genetic backgrounds, they found that the resulting fitness gains were smaller on the more-fit backgrounds than on the less-fit backgrounds. A similar tendency has been seen in other experiments, including one in which Hsin-Hung Chou and colleagues engineered a strain of *Methylobacterium extorquens* to be deficient in growth on methanol and then allowed it to evolve. They then identified four mutations that led to almost a doubling of fitness, constructed all of the possible combinations of those mutations, and measured the fitnesses of the constructed genotypes. Here, too, the fitness gains were usually smaller on the more-fit backgrounds, indicating a pattern of diminishing returns.

Beyond these detailed gene-by-gene analyses of adaptive trajectories, other studies have used the dynamics of adaptation in evolving populations to make inferences about the tempo and sustainability of evolution. In a recent study, Michael Wiser, Noah Ribeck, and Richard Lenski examined fitness changes across a set of 12 populations of *E. coli* as they evolved in and adapted to a nutrient-limited laboratory environment for 50,000 generations. Consistent with the earlier work by Kahn and colleagues, this study supported the role of diminishing-returns epistasis in adaptive evolution. However, the diminishing returns were not sufficient to stop fitness from continuing to increase. Instead, the dynamics of adaptation in this system were well described by a mathematical function called a power law, according to which improvements scale with the logarithm of time. As a consequence, fitness can increase indefinitely, but an ever-declining rate of improvement.

Fitness Effects Due to Possession of Unused Functions

A number of studies have used well-characterized bacterial genotypes to examine the effects on fitness caused by the carriage and expression of superfluous gene functions. These studies have measured the relative fitnesses of (1) bacteria with constitutive (high level) and repressed (low level) expression of enzymes for catabolism of carbon sources in media where those resources are not available; (2) prototrophic bacteria (which produce an amino acid or other required nutrient) and auxotrophic mutants (which cannot produce that nutrient) in media where the required nutrients are supplied; (3) phage-sensitive bacteria and resistant mutants when the phage are absent; and (4) antibiotic-sensitive bacteria and resistant genotypes in media that contain no antibiotics.

These studies have often, but not always, demonstrated substantial fitness disadvantages due to possession of unnecessary gene functions. In some cases where such disadvantages have been detected, they are much greater than can be explained by the energetic costs of synthesizing the extra proteins and other metabolites. For example, a study by Daniel Dykhuizen found that the fitness disadvantage associated with synthesis of the amino acid tryptophan, when it was supplied in the medium, was much greater than could be explained on the basis of energetic costs alone. Evidently, the expression of superfluous functions can sometimes have strong indirect effects, which presumably arise through the disruption of other physiological processes.

The idea that microorganisms may have reduced fitness owing to possession of unnecessary functions has two important practical implications. First, in many bioengineering applications, microorganisms are constructed that constitutively express high levels of some compound (eg, a pharmaceutical) that can be harvested for its commercial value. However, the microorganisms themselves do not benefit from producing that compound, and so any mutant that no longer produces the compound may have a selective advantage. Such a mutation would thus spread through the population and thereby reduce the efficiency of the production process. Second, the spread of antibiotic-resistant bacteria has become a serious concern in public health. It has been proposed that the prudent use of antibiotics, including even the elimination of their use in certain environments (eg, animal feeds), might favor antibiotic-sensitive bacteria, thereby restoring the efficacy of antibiotics. This proposal rests, in part, on the presumption that resistant bacteria are less fit than their sensitive counterparts, in the absence of antibiotic, due to their possession of the superfluous resistance function. This tradeoff often appears to be the case, but sometimes antibiotic-resistant bacteria evolve solutions that reduce or even eliminate the cost of resistance, thus complicating efforts to contain their spread.

Effects Due to Variation in Essential Metabolic Activities

It is clear that the expression of unnecessary metabolic functions is often disadvantageous to a microorganism. An equally important issue concerns the relationship between fitness and the level of expression of functions that are required for growth in a particular environment. This latter issue is more difficult to address experimentally, because it demands careful analyses of subtle differences between strains in their biochemical activities. Daniel Dykhuizen, Antony Dean, and Daniel Hartl performed a pioneering study to examine the relationships between genotype, biochemical activities in a required metabolic pathway, and fitness. Their study examined growth on lactose by genotypes of *E. coli* that varied in levels of expression of the permease used for active uptake of lactose and the β -galactosidase required for hydrolysis of the lactose. (The genotypes were otherwise essentially identical.) Given that both enzymes are necessary for growth on lactose, how do the activities at each step affect the net flux through this metabolic pathway? And how does net flux affect fitness?

Metabolic control theory consists of mathematical models that describe the dynamics across multiple steps in a biochemical pathway. Using this theory, Dykhuizen and colleagues predicted how the net flux through this pathway would depend on the activities of the permease and β -galactosidase enzymes, and they measured these activities for several different genotypes using biochemical methods. They then predicted that the relative fitness of any two genotypes would be directly proportional to their relative fluxes if lactose was provided as the sole energy source. In order to test the theory and its predictions, they estimated the relative fitnesses of the various genotypes in a medium in which lactose was the sole source of energy for growth. The observed fitnesses were very close to the predicted values.

Dykhuizen and Dean have also successfully extended this mechanistic approach to predicting fitness in competition for mixtures of lactose and glucose. However, the results to date (for both single and mixed sugars) were obtained with genotypes in which gene regulation was eliminated in order to simplify the analysis. An important challenge for the future is to include the complex dynamical effects of gene regulation in the models and experiments.

Effects of Genetic Background

It is obvious that the fitness effects caused by particular genetic differences strongly depend on the environment. For example, an antibiotic resistance gene function that is essential for survival and replication of a bacterium in the presence of antibiotic may hinder growth in an antibiotic-free environment. Similarly, the fitness effect that is due to a particular gene function may often depend on the genetic background in which that gene is found.

For example, one study found that different alleles at the 6-phosphogluconate dehydrogenase (6-PGD) locus in *E. coli* had similar fitnesses in a gluconate-limited medium, provided that these alleles were present in a genetic background that also encoded an alternative metabolic pathway for 6-phosphogluconate utilization. In a genetic background where this alternative pathway was defective, however, these alleles had quite variable fitnesses in that same medium.

In another study with *E. coli*, it was observed that the selective disadvantage associated with bacteriophage resistance mutations in a virus-free environment was substantially reduced during several hundred generations of experimental evolution. This fitness improvement resulted from secondary mutations in the genetic background that compensated for the maladaptive side effects of the resistance mutations, but which did not diminish the expression of resistance.

Other studies, including one by Stephanie Schrag, Veronique Perrot, and Bruce Levin, have demonstrated similar compensatory evolution among antibiotic-resistant bacteria. When bacteria resistant to an antibiotic first arise, they are typically less fit in the absence of the antibiotic, thus helping to control their proliferation. Over time, however, the evolving bacteria become very good competitors in the absence of antibiotic while retaining their resistance to antibiotic. That is, the bacteria find ways to “have their cake and eat it, too.” Such compensatory evolution unfortunately makes it more difficult to devise strategies to manage the spread of antibiotic-resistant pathogens.

Speciation and Genetic Exchange

As populations diverge from one another over time, the potential for gene flow between them lessens. The increased barriers to gene flow between more distantly related organisms reflect both molecular processes and selective factors. At the molecular level, highly diverged DNA sequences recombine less efficiently than similar sequences. From the standpoint of selection, genes that evolved in one lineage may not function as well when they are moved into a different lineage, where they must function within a different physiological context. Therefore, when two lineages diverge and adapt to different environments for a sufficiently long time, they become separate species. An experiment by Jeremy Dettman and colleagues examined the effects of adaptation to different environments on the fitness of progeny in the yeast *Saccharomyces cerevisiae*. The researchers generated hybrid progeny by sexually crossing yeast strains, using three different types of strain pairings: (1) two strains that had independently evolved in the same environment; (2) two strains that evolved in different environments; and (3) one evolved strain and its ancestor. The hybrid progeny of strains that had both evolved in the same environment were more fit than the other types of hybrids, while the least fit progeny resulted from crosses between strains that evolved in different environments. These results demonstrate that incipient speciation can occur rapidly as populations adapt to different environments and diverge from one another, so that their hybrid progeny are not well adapted to the environment of either parent.

Over time, another process, called reinforcement, may occur that further separates and isolates two incipient species. Reinforcement occurs when organisms evolve mating preferences so that they become less likely to mate with individuals that are ecologically and genetically distinct, thereby avoiding the production of mal-adapted hybrid offspring. In another experiment with yeast, Jun-Yi Leu and Andrew Murray showed the rapid evolution of mate discrimination. After only a few dozen rounds of selection for assortative mating, yeast cells had evolved that were five times more likely to mate with their own type than with the ancestor.

Genomic Analyses of Experimental Evolution

As technologies change, so do the questions that biologists can address. Our understanding of the extent and patterns of genetic diversity has grown with each new advance. For many years, geneticists had to rely on differences that were visible to the naked eye – for example, the round and wrinkled seeds, and white and purple flowers, of the pea plant that Gregor Mendel studied to discover the basic laws of inheritance in plants and animals. Several decades ago, biochemists discovered they could discern subtle differences in proteins, caused by mutations in the genes that encode them, by examining how the variant proteins moved through gels that were subject to electrical fields. This approach revolutionized biology by demonstrating tremendous levels of genetic diversity in almost every species that was investigated, from bacteria to humans. More recently, the ability to sequence DNA molecules now allows scientists to examine and compare the hereditary information of organisms at its most fundamental level. It has become possible to sequence genes isolated directly from the environment, allowing ecologists to examine patterns of diversity even among microbes that have never been directly observed or cultured. It has also become possible to sequence the entire genome of any organism. With improving technologies and declining costs, it is becoming feasible to pursue whole-genome sequencing to discover and investigate all of the genetic changes that occur during laboratory-based evolution experiments.

A fascinating question in evolution – and one that has benefited from the improving genomic technologies – concerns the reproducibility of evolutionary outcomes. The late paleontologist Stephen Jay Gould imagined the thought experiment of “replaying life’s tape” to address this question. Of course, it is impossible to rerun evolution for billions of years on the scale of an entire planet, but with microbes one can perform careful experiments to ask whether replicated populations that start with the same ancestor and evolve in the same environment will arrive at the same or different solutions to the challenges they face. A long-term study by Richard Lenski and colleagues has monitored the evolution of 12 initially identical populations of *E. coli* as they evolved in and adapted to the same laboratory environment for over 60,000 generations. They identified many parallel, or repeatable, changes in the phenotypes of the evolving lineages, including improved competitiveness in the glucose-based medium where they evolved, reduced performance on certain other sugars including ribose and maltose, larger cell volumes, altered supercoiling of their chromosomes, and so on. Based on the tremendous advances in DNA sequencing technology, a recent paper by Olivier Tenaillon, Jeffrey Barrick, and colleagues analyzed the complete genomes of 264 isolates from the first 50,000 generations across the replicate populations, allowing them to characterize the long-term dynamics of genome evolution. The authors found that many genes had acquired mutations in several or even all of the evolved lines, even though most genes acquired no substitutions in any of the lines. These data indicate a high degree of evolutionary reproducibility even at the genetic level.

Holly Wichman, James Bull and colleagues previously documented even more striking evolutionary reproducibility in the bacteriophage (ϕ)X174. In this case, the reproducibility, or parallelism, often extended to the nucleotide level. Christopher Herring, Bernhard Palsson and colleagues have used new methods for rapidly resequencing entire bacterial genomes to identify several genes that changed repeatedly in short-term experiments in which *E. coli* evolved in and adapted to a glycerol-based medium. Gregory Lang and colleagues also used this approach with the yeast *S. cerevisiae*, finding many cases in which multiple mutations arise at similar times and compete to become fixed within a given population. They also found a subset of genes that showed striking parallelism as mutational targets across dozens of replicate populations. Outside the laboratory, these new sequencing approaches have been used to study evolutionary dynamics in clinical settings, which sometimes provide a so-called “natural experiment” in which multiple infected hosts are analogous to replicate culture vessels. For example, Tami Lieberman and colleagues sequenced over a hundred genomes of pathogenic *Burkholderia dolorosa* that were isolated over many years from the lungs of patients with cystic fibrosis, finding a number of genes that underwent parallel evolution during the adaptation to different individual hosts.

Genome-level resequencing was also used by Gregory Velicer and colleagues to discover mutations that arose during a two-stage evolution experiment with the bacterium *Myxococcus xanthus*. This species is fascinating because cells, when they are starving, form multicellular aggregations. Some of the cells in these aggregations differentiate into stress-tolerant spores that can be dispersed and germinated in more favorable environments, but the majority of cells die while forming a mound-like structure that elevates the spores and helps them disperse. In the first stage of their experiment, Velicer and colleagues evolved *M. xanthus* strains that “cheated” on their progenitors during aggregation and differentiation. By themselves, these cheaters were poor at aggregating and producing spores, but when they were mixed with their cooperative progenitors, the cheaters were disproportionately likely to end up among the surviving spores. In the second stage of this evolution experiment, Velicer and colleagues found one cheater-derived strain that had recovered the ability to cooperate, although its mechanism of cooperation was somewhat different from the ancestral cooperator. By resequencing the genomes of both the evolved cheater and the restored cooperator, and comparing them to the ancestral genome, they found 14 mutations that led to the cheater, but only a single mutation – although obviously an important one – was responsible for the evolved restoration of the cooperative behavior.

Genetic Variation Within Populations

In nature, there exists abundant genetic variation in most species, including microorganisms. Some of this variation exists within local populations, while other variation may distinguish one population from another. This section describes some of the dynamic processes that influence genetic variation within populations.

Transient Polymorphisms

A population is polymorphic whenever two or more genotypes are present above some defined frequency (eg, 1%). A polymorphism arises whenever an advantageous mutation is increasing in frequency relative to the ancestral allele. This type of polymorphism is called transient, because eventually the favored allele will exclude the ancestral allele by natural selection.

Selective Neutrality

At the other extreme, some polymorphisms may exist almost indefinitely precisely because the alleles that are involved have little or no differential effect on fitness. Such selectively neutral alleles are subject only to genetic drift. Daniel Dykhuizen and Daniel Hartl sought to determine whether some polymorphic loci in natural populations of *E. coli* might exist because of selective neutrality, or whether other explanations are needed. To that end, naturally occurring alleles at certain loci were moved into a common genetic background, and the fitness effects associated with the various alleles were determined. Even when the bacteria were grown under conditions where growth was directly dependent on the particular enzymes encoded by these loci, there were often no discernible effects on fitness due to the different alleles. These results therefore support the hypothesis that random genetic drift is responsible for some of the genetic variation that is present in natural populations.

Frequency-Dependent Selection

In the course of growth and competition in a particular environment, microorganisms modify their environment through the depletion of resources, the secretion of metabolites, and so on. When this happens, the relative fitness of genotypes may depend on the frequency with which they are represented in a population, and selection is said to be frequency-dependent. Frequency-dependent selection can give rise to several different patterns of genetic variation.

Stable equilibria

Two (or more) genotypes can coexist indefinitely when each has some competitive advantage that disappears as that genotype becomes more common. In that case, each genotype can invade a population consisting largely of the other genotype but cannot exclude that other genotype, so that a stable equilibrium results.

Several different ecological interactions can promote a stable equilibrium. For example, an environment may contain two different resources. If one genotype is better at exploiting one resource and another genotype is superior in competition for the second resource, then whichever genotype is rarer will tend to have more resource available to it, thereby promoting their stable coexistence. In some cases, a resource that is essential for one genotype may be produced as a metabolic by-product of growth by another genotype; such interactions are often called cross-feeding. Stable coexistence of genotypes in one population can also occur when the environment contains a population of predators (or parasites); predator-mediated coexistence requires that one of the prey genotypes be better at exploiting the limiting resource while the other prey genotype is more resistant to the predator. The evolution of two or more stably coexisting bacterial types from a single ancestral type has been demonstrated in several experiments involving both cross-feeding and predator-prey interactions.

A striking example of the rapid evolution of several stably coexisting genotypes comes from an experiment on *Pseudomonas fluorescens* performed by Paul Rainey and Michael Travisano. The experiment started with a single clone that was placed in a static (unshaken) flask containing a nutritionally rich liquid medium. Within a few days, the bacteria evolved into three distinct genotypes that could be distinguished by the appearance of their colonies, and these types then coexisted with one another. By reconstituting the various combinations of these three types, the authors showed that each type had a selective advantage when it was rare relative to one or both of the other types. As a consequence, each genotype could invade and coexist with the others, so that a stable community was formed. However, if the medium and cells were thoroughly mixed by physically shaking the flask, then this coexistence was disrupted and one genotype prevailed. The three genotypes coexisted in the static flask because they had evolved different abilities to exploit gradients, such as in oxygen concentration, which were generated by the organisms' metabolic activities in concert with the physical environment. When these gradients were eliminated by continually shaking the flask, stable coexistence of the three genotypes was impossible.

Unstable equilibria

Those ecological interactions that promote the stable coexistence of two or more genotypes contribute to the maintenance of genetic variation in populations. However, certain ecological interactions give rise to unstable equilibria. An unstable equilibrium exists when each of two genotypes prevents the other from increasing in number. Such interactions do not promote polymorphisms

within a local population. However, they may contribute to the maintenance of genetic differences between populations, because neither type can invade a resident population of the other type.

One form of ecological interaction that can give rise to an unstable equilibrium is interference competition. This interaction occurs when one genotype produces a toxic substance that inhibits the growth of competing genotypes; it is distinguished from exploitative (scramble) competition, which occurs by the depletion of resources. Many microorganisms secrete such toxins, including fungi that produce antibiotics. Similarly, some strains of *E. coli* produce colicins that kill some competing strains of *E. coli*, but to which the producing genotypes are immune. The producing types, when common, make so much toxins that they can eliminate a sensitive strain that is more efficient in exploitative competition. When the producing cells are rare, however, the cost of their colicin production is greater than the benefit of the resource that becomes available by the killing of sensitive cells, and the producing type loses out to the more efficient colicin-sensitive competitor. The outcome of competition between colicin-producing and sensitive strains also depends on the physical structure of the environment, as shown in experiments by Lin Chao and Bruce Levin. In particular, the advantage shifts to the colicin-producing cells on agar surfaces, even when they are rare, because the resources made available by the killing action of colicins accrue locally to the producers, rather than being dispersed evenly as in a well-stirred liquid medium.

Nontransitive interactions

In some cases, the frequency-dependent interactions among three or more genotypes are so complex that they become nontransitive. For example, genotype *A* out-competes genotype *B*, and genotype *B* out-competes genotype *C*, but genotype *C* out-competes genotype *A*. A familiar example is the game of rock-paper-scissors, in which rock beats scissors, scissors beat paper, and paper beats rock. Benjamin Kerr, Brendan Bohannan and colleagues studied an example of this game played by three strains of *E. coli* on the surface of agar plates. One strain produced a toxic colicin, while the second strain was sensitive to the colicin. The third strain was resistant to the colicin, although it did not produce any toxin. In pairwise interactions, the colicin-producing strain out-competes the sensitive strain by poisoning it. The resistant strain out-competes the producing strain by not wasting resources to produce the colicin, as both strains are resistant to it. The sensitive strain, in turn, out-competes the resistant strain because there is no colicin around, and the resistant strain pays a fitness cost for its resistance. This research team further showed, both by experiments and in computer simulations, that the three strains could coexist with one another only in a spatially structured environment, such as on the surface of an agar plate. By contrast, in a well-mixed liquid medium, one strain dominates, although the identity of the winner depends on the initial abundances.

As another example, Charlotte Paquin and Julian Adams found nontransitive interactions in populations of the yeast, *S. cerevisiae*, that were evolving in chemostats fed with glucose as a sole carbon source. Nontransitive interactions can lead to situations in which the average fitness of an evolving population declines relative to some distant ancestor, even though each successive dominant genotype has increased fitness relative to its immediate predecessor. Indeed, Paquin and Adams observed precisely this phenomenon.

Evolution in a Changing Environment

Most evolution experiments operate within a controlled, defined environment, which facilitates the analysis and interpretation of these experiments. However, many environments change over time owing to either external processes, such as a change in temperature, or internal processes, such as resource depletion or coevolution of interacting species. This section examines research on the evolution of bacteria in response to prolonged resource deprivation, while the next section will address the coevolution of interacting species.

When bacteria are inoculated into fresh medium, they grow exponentially until they exhaust the available nutrients, at which point the cells typically enter a “stationary” phase during which they neither grow nor die, at least for many hours or even days. However, if the bacteria are left in the nutrient-depleted medium indefinitely, they eventually enter a death phase, although not all the cells necessarily die even after a very long time. Roberto Kolter and Steven Finkel studied the ecological and evolutionary dynamics in long-term cultures of *E. coli* that were grown in a nutrient-rich medium and then left for over 5 years without additional nutrients, except that sterile water was added occasionally to compensate for evaporation. Some 99% of the cells died over the first few weeks of the death phase. If that rate of decline had continued throughout the experiment, then there would soon have been no survivors at all. However, Kolter and Finkel found that the surviving cells entered a sort of second stationary phase, in which the population declined only very slowly. During this period, the rates of cell division and death were nearly equal, so that the population was dynamic rather than static. Moreover, the environment itself changed continually owing to the buildup and breakdown of metabolic by-products released by both living and dying cells. This changing environment, in turn, favored mutants that were better able to survive and grow under these challenging conditions than was the strain used to begin this experiment. The authors called these winners “GASP” mutants because they had a growth advantage in stationary phase (GASP). Further analyses of this system found multiple waves of GASP mutants that arose and swept to high frequency in the population, only to be displaced later by other, even tougher, mutants. Thus, many different mutations can produce GASP phenotypes, and the various mutants differ in the details of their physiological and ecological advantages.

Coevolution of Interacting Genomes and Species

Microorganisms in nature rarely, if ever, exist as single species, as they are usually studied in the laboratory. Rather, they exist in complex communities of many interacting populations. Some interactions are exploitative, such that one population makes its living by parasitizing or preying upon another population. Other interactions are mutualistic, such that each population obtains some benefit from its association with the other. In many cases, these interactions are plastic both genetically and ecologically. For example, a single mutation in a bacterium may render it resistant to lethal infection by a bacteriophage. And a plasmid that confers antibiotic resistance may be beneficial to its bacterial host in an antibiotic-containing environment but detrimental in an antibiotic-free environment.

As a consequence of this variability, microorganisms have proven useful for investigating questions about the coevolution of interacting populations. Are there evolutionary “arms races” between host defenses and parasite counter defenses? Why are some parasites so virulent to their hosts, whereas others are relatively benign? How can mutualistic interactions evolve, if natural selection favors “selfish” genes that replicate themselves even at the expense of others?

Exploitative Interactions

A number of studies have demonstrated the stable coexistence of virulent bacteriophage (lytic viruses) and bacteria in continuous culture. In these studies, the virus population may hold the bacterial population in check at a density that is several orders of magnitude below the density that would be permitted by the available resource if viruses were not present. In most cases, however, bacterial mutants eventually appear that are resistant to the virus, and these mutants have a pronounced selective advantage over their virus-sensitive progenitors. The proliferation of bacteria that are resistant to infection by the original virus provides a selective advantage to host-range viral mutants, which are capable of infecting the resistant bacteria. Thus, one can imagine, in principle, an endless “arms race” between resistant bacteria and extended host-range viruses.

In fact, there are constraints that often preclude this outcome. Experiments performed by Lin Chao, Richard Lenski, and Bruce Levin using *E. coli* and several lytic viruses found that bacterial mutants eventually evolved for which it was very difficult or impossible to isolate corresponding host-range viral mutants. This asymmetry may arise because bacterial resistance can occur via mutations that cause either the structural alteration or the complete loss of certain receptors on the bacterial surface, whereas viral host-range mutations can counter only the former. Despite this asymmetry, these experiments also demonstrated that the virus population often persisted because the virus-resistant bacterial mutants were less efficient than their sensitive progenitors in competing for limiting resources. In such cases, the result was a dynamic equilibrium, in which the growth-rate advantage of the sensitive bacteria relative to the resistant mutants was offset by death due to viral infection. Such tradeoffs between competitiveness and resistance commonly occur, because the same receptors used by viruses to adsorb to the cell envelope often serve to transport nutrients into the cell or to maintain its structural integrity.

A widely held belief is that a predator or parasite that is too efficient or virulent will drive its prey or host population extinct, thereby causing its own demise. However, virulent phage often coexists with bacteria, even though successful reproduction of the virus is lethal to the infected bacterium. Moreover, the process of natural selection does not involve foresight, so the mere prospect of extinction cannot deter the evolution of more efficient predators or more virulent parasites. Nevertheless, there exist many viruses (lysogenic and filamentous bacteriophage) that are replicated alongside the host genome, and whose infections, although deleterious, are not necessarily lethal. These viruses, as well as conjugative plasmids, have life cycles that include both horizontal (infectious) and vertical (intergenerational) transmission.

At present, the evolutionary forces that favor these alternative modes of transmission are not fully understood. One factor that is thought to be important is the density of hosts. If susceptible hosts are abundant, then there are many opportunities for horizontal transmission. In that case, selection favors those parasites that replicate and infectiously transmit themselves most rapidly, regardless of the consequences of these activities for the host's fitness. On the other hand, if susceptible hosts are scarce, then horizontal transmission becomes infrequent. Vertical transmission, by contrast, does not depend upon the parasite or its progeny finding another host. Instead, the success of a vertically transmitted parasite is determined by the success of its infected host. The greater the burden that such a parasite imposes on its host, the slower the host can reproduce its own genome and that of the parasite. Hence, when the density of susceptible hosts is low, selection may favor those parasites that minimize their replicative and infectious activities, and thereby minimize their deleterious effects on the host.

Two studies sought to test this hypothesis by manipulating the supply of susceptible hosts. One experiment, by Jim Bull and colleagues, with a filamentous bacteriophage supported the hypothesis. The other study, by Paul Turner and Richard Lenski, used a conjugative plasmid, and their experiment did not support that hypothesis, for reasons that are unclear. However, both studies demonstrated genetically encoded tradeoffs between the parasites' rates of horizontal and vertical transmission. That is, parasites that were transmitted between individual hosts at higher rates reduced the host's growth rate – and hence their own vertical transmission – more severely than did parasites that were infectiously transmitted at lower rates.

In addition to subtle changes in the interaction between a virus and its current host, evolution can occur when a virus evolves the ability to infect a different host species. Most viruses are severely constrained in the organisms that they can infect because they must enter their host via specific proteins or other receptors on the host's cell surface, and these receptors typically differ between host species. Two viral genomes can only recombine genetically when they both infect the same host. Therefore, if a virus evolves the new

ability to infect a different host species and, moreover, loses its ability to infect its previous host, then this host shift may lead to speciation, whereby a single virus population eventually evolves to become two distinct types of virus.

A study by Wayne Crill, Holly Wichman, and Jim Bull examined the adaptation of a virus to two different host species. They alternated a bacteriophage population between two bacterial hosts, *E. coli* and *Salmonella enterica*. The experiment was designed so that the virus saw only “naïve” bacteria that had not previously been exposed to the virus; hence, the bacteria could not evolve resistance that might complicate their analysis of the evolving virus. Because the viral genome is small, the authors could completely sequence several isolates of the virus after each round of their adaptation to the alternating hosts. The authors found a single base pair in the virus genome that alternated in perfect concordance with the host species to which the virus had most recently adapted. Owing to this and other mutations, viral growth rate was always higher on the current host than on the alternate host. However, there was a strong asymmetry in this host-specific adaptation. Specifically, adaptation to *S. enterica* led to reduce viral growth on *E. coli*, but adaptation to *E. coli* did not cause a comparable reduction in growth on *S. enterica*. This finding has potential relevance for the production of vaccines, because it is common practice to produce weakened versions of infectious viruses by adapting them to new cell types, and then using these attenuated viruses in vaccines. If viral adaptation to a new host type does not always impair viral growth on its usual host, then it becomes all the more necessary to test carefully the safety of such putatively attenuated viruses. More generally, these results show that even single mutations can sometimes allow viruses to infect new host species, a finding that is of interest not only for understanding evolution but also to public health.

Mutualistic Interactions

It has been proposed that many mutualisms evolved from formerly antagonistic interactions. In fact, mathematical models predict that, at low host densities, genetic elements such as plasmids and phage can persist only if they are beneficial to their host. Many plasmids encode functions useful to their bacterial hosts, including resistance to antibiotics, catabolic pathways, production of bacteriocins, and so on. Also, some plasmids are unable to promote conjugation, thus relying exclusively on vertical transmission. This limitation requires that the plasmid does not harm its host, because any plasmid-free derivative would otherwise out-compete those cells that carry a costly plasmid. Indeed, several studies have found unexpected competitive advantages for bacteria that are infected by plasmids, transposons, and even temperate phage, relative to cells that are not infected but otherwise genetically identical.

Two studies have even demonstrated the evolution of mutualistic interactions from formerly antagonistic associations. Kwang Jeon showed that the growth of the protist *Ameba proteus* was initially greatly reduced by a virulent bacterial infection. The harmful effects of the bacteria were diminished, however, by propagating the infected amoebae for several years. In fact, the amoebae eventually became dependent on the bacterial infection for their viability. In another study, Judith Bouma and Richard Lenski found that a certain plasmid initially reduced the fitness of its *E. coli* host in antibiotic-free medium. However, the plasmid enhanced the fitness of its host in this same medium after 500 generations of experimental evolution. Interestingly, the mutation responsible for the newly evolved mutualistic interaction was in the host, not in the plasmid. Both of these experiments show that hosts can become dependent on, or otherwise benefit from, formerly parasitic genomes, thus giving rise to mutualistic interactions.

Evolution of New Metabolic Functions

Microbes exhibit a tremendous diversity of metabolic activities, some of which function in degradative pathways (catabolism) while others work in synthetic pathways (anabolism). How has this diversity evolved? One area of research in the field of experimental evolution seeks to elucidate the various processes by which microorganisms can acquire new metabolic functions. This research is timely as humans seek to employ certain microbes that degrade toxic pollutants in the environment, and to harness others that may be useful in the production of biofuels.

Acquisition by Gene Transfer

Perhaps the simplest way in which a microorganism can acquire some new metabolic function is by gene transfer from another microorganism that already encodes that function. For example, antibiotic resistance functions are often encoded by plasmids, which are transmitted from donors to recipients by conjugation. However, acquiring new functions by gene transfer is not always so simple. Biodegradation of certain recalcitrant compounds may require the complex coordination of several steps in a biochemical pathway, which are encoded by complementary genes from two (or more) different microorganisms. The acquisition of activities that depend on such pathways may require not only genetic exchange, but also subsequent refinement of the new function by mutation and natural selection.

Changes in regulatory and structural genes

In a number of studies, microorganisms have been shown to evolve new metabolic functions without any horizontal gene exchange. The evolution of these new functions often occurs by selection for mutations in existing regulatory or structural genes that previously encoded some other function. For example, the bacterium *Klebsiella aerogenes* cannot normally grow on the sugar D-arabinose, although it does possess an enzyme, isomerase, that is able to catalyze the conversion of D-arabinose into an

intermediate, D-ribulose, which can be further degraded to provide energy to the cell. This isomerase is normally expressed at a very low level that does not permit growth on D-arabinose. Robert Mortlock and colleagues demonstrated that mutations in regulatory genes that increase the level of expression of this isomerase are sufficient to enable *K. aerogenes* to grow on D-arabinose. They also showed that the ability to grow on D-arabinose could be further improved by certain mutations in the structural gene that change the amino acid sequence of the isomerase in ways that improve its efficiency in converting D-arabinose into D-ribulose.

Mutations that place existing genes in a new regulatory context can also have profound effects on an organism's phenotype. After more than 30,000 generations into the long-term evolution experiment with *E. coli* discussed elsewhere, one of the 12 populations grew visibly turbid, as bacteria began to grow on citrate that is present in the medium as a chelating agent. At first this growth was thought to indicate contamination, because *E. coli* cannot normally grow on citrate in an oxygen-containing environment. However, work led by Zachary Blount showed that a subpopulation had evolved the ability to consume the citrate in the medium. Blount's work further showed that a genetic rearrangement – specifically, tandem duplication – had placed a previously unexpressed gene encoding a citrate transporter protein under the control of a promoter that was expressed in the presence of oxygen as the cells exhausted the glucose on which they fed. Even with this mutation, efficient growth on citrate was contingent on one or more mutations that had evolved earlier in this lineage, and subsequent mutations were also important for the bacteria to effectively exploit its new ecological niche.

These studies, as well as other experiments and comparative analyses, show that the evolution of new metabolic functions often involves “borrowing” gene products that were previously used for other functions. It is not surprising that this process may sometimes also encroach upon, and disrupt, the previous function. Such encroachment could, in turn, favor gene duplications, whereby a single copy of an ancestral gene gives rise to two copies, each of which may then evolve toward different metabolic capabilities.

Evolution of Genetic Systems

The process of adaptation by natural selection requires genetic variation in traits that influence the survival and reproduction of organisms. As discussed earlier, the two sources of genetic variation are mutation and mixis. Rates of mutation and mixis depend not only on environmental factors (eg, ultraviolet irradiation), but also on properties of the “genetic system” intrinsic to the organism itself. Here, genetic system refers to all those aspects of the physiology, biochemistry, and reproductive biology of an organism that affect rates of mutation and mixis. For example, organisms have mechanisms of varying efficacy to promote the accurate replication and repair of their DNA. And while sex is an integral part of reproduction for some organisms, many others reproduce asexually, so that the progeny are usually identical to their parent and siblings.

Some of the most interesting questions in evolutionary biology concern the significance and evolutionary consequences of alternative genetic systems. Why do some organisms reproduce sexually, whereas others reproduce asexually? If mutation generates variation that is necessary for adaptation by a population, but most mutations have deleterious effects on the individual, then what mutation rate is optimal? Might organisms somehow be able to choose only those mutations that are beneficial to them, given their present circumstances?

Sexuality and Mixis

Sexual reproduction imposes several costs relative to asexual reproduction. These costs include finding a mate, the risk of disease transmission, and, in higher organisms, the genetic dilution that occurs because a female produces an offspring that carries only half of her genes. Therefore, biologists have long sought to understand the advantages for sexual reproduction that could overcome these disadvantages. Numerous hypotheses have been proposed, and all of them depend, in one way or another, on the genetic variation that results from mixis. Most efforts to test these hypotheses have relied on comparing distributions of sexual and asexual organisms to find variables that correlate with reproductive mode. However, several experiments have tested the evolutionary consequences of mixis using microbes in which one can manipulate the extent of intergenomic recombination.

For example, mixis in viruses can be experimentally manipulated by varying the multiplicity of infection (MOI) of host cells, since recombination of viral genotypes can occur only if two or more viruses infect the same host cell. An experimental study by Russell Malmberg compared the rate of adaptive evolution in bacteriophage populations propagated at high and low MOI; the total number of viruses per population was standardized for both treatments. The average fitness increased more rapidly under the high-MOI (equal to high recombination) treatment than under the low-MOI (equal to low recombination) treatment. This result is consistent with the hypothesis that sexual populations can adapt more rapidly than asexual ones because two or more beneficial mutations can be incorporated simultaneously in the former, but only sequentially in the latter.

Another experiment indicates that the benefit of mixis in accelerating adaptive evolution may depend on the environment. Matthew Goddard, Charles Godfray, and Austin Burt compared the rate of fitness improvement in evolving sexual and asexual populations of the yeast *S. cerevisiae*. By deleting two genes in the yeast, they were able to construct an asexual version that could not undergo meiosis. They then established separate populations of sexual and asexual yeast in both harsh and benign environments, and allowed the yeast to evolve for several hundred generations. Neither sexual nor asexual strains showed significant improvement in the benign environment, implying that they were already well adapted to those conditions. However, both strains adapted to the

harsh environment, with the rate of improvement consistently greater for the sexual than the asexual populations. This experiment suggests, therefore, that genetic recombination can be especially important for adaptation to stressful and changing environments.

Some experiments have suggested that another advantage of mixis may occur when the rate of deleterious mutation is high and the effective population size is very small. Such conditions may apply especially to microorganisms with high error rates during replication (eg, RNA viruses) or those with large genomes (eg, protozoa), if their populations experience periodic “bottlenecks.” In these cases, deleterious mutations tend to accumulate in asexual lineages, a process called “Muller’s ratchet” (after the geneticist, H. J. Muller, who first described this phenomenon). However, even occasional mixis can purge lineages of their accumulated load of deleterious mutations, as demonstrated by Lin Chao and colleagues using a segmented RNA virus that infects bacteria. This effect occurs because two recombining genomes may each complement the deleterious mutations that are present in the other, thereby generating some progeny that have a reduced load of deleterious mutations (as well as other progeny with an increased load, which will be removed by natural selection).

In some cases, mixis might not be an adaptation to recombine genes but rather a coincidental consequence of the movement between cells of parasitic entities. In many bacteria, for example, mixis occurs only when cells are infected by viruses (transduction) or plasmids (conjugation). The new combinations of chromosomal genes that sometimes result from such infections may occasionally be advantageous. However, one cannot view phage and plasmids as benevolent agents of bacterial carnal pleasure, because these infectious agents often harm or even kill their hosts.

Evolutionary Effects of Mutator Genes

“Mutator” genes increase the mutation rate throughout an organism’s genome by disrupting DNA repair functions. Experiments performed by Lin Chao and others have investigated the effect of mutator genes on bacterial evolution. These studies have revealed a pattern that seems, at first glance, rather curious. When a mutator gene is introduced in a population above a certain initial frequency (eg, 0.1%), it tends to increase in frequency over the long term. However, if that same gene is introduced at a frequency below that threshold, then it typically goes extinct.

What causes this curious effect? In a sense, there is an evolutionary race between two clones, with and without the mutator gene, to see which one gets the next beneficial mutation. The rate of appearance of new mutations for each clone depends on the product of its population size, N , and its mutation rate, u . When the ratio of mutation rates for the mutator and nonmutator clones, u'/u , is greater than the inverse ratio of their population sizes, N/N' , then the mutator clone is more likely to have the next beneficial mutation and thus prevail over the long term. When u'/u is less than N/N' , the nonmutator clone, by virtue of its greater numbers, is likely to produce the next beneficial mutation and thereby exclude the mutator clone.

However, this explanation presents a problem for understanding the evolution of mutators in nature, where they are moderately prevalent in some circumstances. If mutator genes are useful only when they are common, then how do they become common in the first place? Mathematical models and evolution experiments with bacteria indicate that a process called “hitchhiking” can resolve this paradox. In hitchhiking, a deleterious mutation (such as the one that disrupts DNA repair) gets carried along to high frequency if it is genetically linked to a beneficial mutation. In bacteria, which usually have a single chromosome and reproduce asexually, the entire genome is effectively linked. Moreover, a mutator gene is more likely than any other deleterious mutation to be associated with a new beneficial mutation because of the high mutation rate it causes. It is unlikely that any particular mutation that produces a mutator will yield a beneficial mutation that allows the mutator to hitchhike. Given enough time, however, one “lucky” mutator may do so, and the mutator gene can then increase in frequency by hitchhiking with the beneficial mutation that it caused.

It has also been proposed that mutator genes may be more common in pathogenic bacteria than in their nonpathogenic counterparts. The idea is that pathogenic bacteria face especially rapidly changing selective conditions owing to immunological and other host defenses. By having a high mutation rate, pathogens would have a better chance of evolving a counter defense. This explanation also fits well with the hitchhiking hypothesis, because every change in the host that favors a new mutation in the pathogen population creates an opportunity for a mutator allele to hitchhike to high frequency. By contrast, for an organism living in a constant environment to which it is already adapted, beneficial mutations would be much rarer and hence there would be fewer opportunities for a mutator gene to hitchhike. Antonio Oliver, Fernando Baquero, Jesús Blázquez, and colleagues examined the frequency of mutator genes in samples of *Pseudomonas aeruginosa*, a bacterial species that often causes chronic (long-term) lung infections in people with cystic fibrosis. This same species is common in the environment, and it can cause acute (short-term) infections in patients with severe burns or otherwise weakened immune systems. The authors documented a much higher frequency of mutator clones in samples from patients with chronic infections, which supports the hypothesis that frequent changes in host immunity and antibiotic regimens can promote the evolution of high mutation rates.

An experimental study by Csaba Pal, Angus Buckling, and colleagues examined the effect of viral parasites on the evolution of mutation rates in bacteria. They found that *P. fluorescens* that were coevolving in environments with bacteriophage present were much more likely to become mutators than were bacteria that were evolving in the absence of the bacteriophage. This study also supports the general hypothesis that rapidly changing environments – including coevolving parasites as well as hosts – can favor the evolution of elevated mutation rates.

Thus, aspects of genetic systems that increase variation – whether by mutation or mixis – may accelerate adaptive evolution. On the other hand, mutation and mixis can also break down genotypes that are already well adapted to particular environments. The evolution of genetic systems may often reflect the balance between these opposing pressures.

Directed Mutations?

The experiments of Luria and Delbrück and the Lederbergs demonstrated that mutations arose before bacteria were exposed to a selective agent, and thus the mutations were not a response by the bacteria to that agent. However, in 1988, John Cairns and colleagues called into question the generality of random mutation in bacteria. Their paper and some other studies seemed to show that certain mutations occurred only (or more often) when the mutants were favored, and such mutations were called “directed.” However, several subsequent experiments indicated that some of the evidence for directed mutation was flawed or misinterpreted, and this subject became very controversial. However, there is now widespread agreement that the most radical hypotheses put forward to explain this phenomenon – for example, a reverse flow of information from the environment through proteins and RNA back to the DNA – are incorrect.

Nonetheless, this controversy generated renewed interest in bacterial mutation, especially the mechanisms by which a cell might exercise some control over the mutational process. Attention became focused on understanding the effects of stress, such as due to starvation, on DNA repair and mutation, as well as the extent of variation among local DNA sequences in their mutability. For example, numerous studies have documented unusually high mutation rates in short repeated sequences (eg, TTTT); the mutations are typically frameshift events involving the loss or gain of a repeated element, and they occur via the slippage of DNA strands during replication. These hypermutable sequences are not distributed randomly throughout bacterial genomes. Rather, they are found more often in genes encoding products (such as fimbriae and lipopolysaccharides on the cell surface) that are involved in pathogenicity and evasion of host immune surveillance. This distribution suggests that bacteria have evolved a simple but effective strategy to increase the mutation rate in genes that help them cope with unpredictable aspects of the environment, without inflating the load of deleterious mutations in “housekeeping” genes whose products interact predictably with the environment. These mutations are apparently random insofar as a particular mutation does not occur as a direct response to an immediate and specific need, but they are nonrandom in their genomic distribution and may thereby promote a more favorable balance between evolutionary flexibility and conservatism.

Evolving Multicellularity

Experimental evolution is also being used to investigate certain major transitions in evolution. In a pioneering study, William Ratcliffe, Michael Travisano, and colleagues demonstrated that a simple selection procedure that favored faster settling in the yeast *S. cerevisiae* led to multicellular yeast. That is, those individuals that reached the bottom of the culture vessel the fastest were used to seed the next generation. In principle, this procedure might have favored sticky cells that simply adhered to one another. However, subsequent analyses revealed that the clusters – shaped almost like snowflakes – were formed by cells that did not completely separate after division. Moreover, these clusters continue to replicate as multicellular configurations, with daughter clusters breaking off from an existing cluster, and then growing in size before releasing their own multicellular propagules. The ability to observe such a major transition in the laboratory demonstrates the power of experimental approaches to addressing evolutionary questions.

Glossary

AB structure–function Structure–function organization of most bacterial exotoxins; the A domain comprises a catalytic activity and the B domain comprises the binding and translocation domains.

Exotoxin A soluble protein produced by a microorganism that can enter a host cell and catalyze the covalent modification of a cellular component to alter host-cell physiology.

Heat-stable enterotoxins Soluble peptides that are secreted by bacteria, which bind to host cells and stimulate a signal transduction pathway within that cell.

Mechanism of action The specific reaction by which each exotoxin modifies a host-cell component, such as the ADP-ribosylation of elongation factor-2 by diphtheria toxin.

N-terminal and C-terminal Bacterial toxins are often organized into distinct domains termed the amino-terminal (N-terminal) and carboxy-terminal (C-terminal) domain based upon their location within the primary amino acid sequence of the toxin.

Pore-forming toxins Soluble monomeric proteins that are secreted by bacteria, which bind to the surface of the host cell and oligomerize to form a pore to release soluble components from the host cell.

Posttranslational modification A covalent modification to a cellular component that occurs subsequent to its synthesis.

Proenzyme The form in which exotoxins are secreted by bacteria; these are processed to exhibit catalytic activity.

Superantigens Soluble proteins that are secreted by bacteria and bind to the major histocompatibility complex of antigen presenting cells outside the peptide-binding groove. This complex binds to the T cell receptor of other T lymphocytes, which stimulates antigen-independent poly-clonal proliferation of T lymphocytes and cytokine secretion.

Toxoid The detoxified form of an exotoxin that is used for immunization. Conventional toxoiding is achieved with chemicals such as formalin; genetic engineering approaches can also produce toxoids.

Type III secreted cytotoxins Soluble proteins that are translocated into the host-cell cytoplasm via a type III secretion apparatus by host-cell surface-bound bacteria. Subsequent studies identified several analogous secretion systems termed the type IV, V, and VI secretion systems which also deliver cytotoxins from the bacterium into the host cell.

Vaccination The administration of an immunogen (toxoid) to stimulate an immune response that protects the host from infection by the microorganism that produces the immunogen.

Exotoxins are a group of soluble proteins which are secreted by bacteria that enter host cells, and catalyze the covalent modification of a host-cell component(s) to alter the host-cell physiology. Both Gram-negative and Gram-positive bacteria produce exotoxins. A specific bacterial pathogen may produce a single exotoxin or multiple exotoxins. Each exotoxin possesses a unique mechanism of action, which is responsible for the elicitation of a unique pathology. Thus, the role of exotoxins in bacterial pathogenesis is unique to each exotoxin. For example, *Corynebacterium diphtheriae* produces diphtheria toxin, which is responsible for the systemic pathology associated with diphtheria, whereas *Vibrio cholerae* produces cholera toxin, which is responsible for the diarrheal pathology associated with cholera. Exotoxins vary in their cytotoxic potency, with the clostridial neurotoxins being the most potent exotoxins for humans. Exotoxins also vary with respect to the host that can be intoxicated. Exotoxin A of *Pseudomonas aeruginosa* can intoxicate cells from numerous species, whereas other toxins, such as diphtheria toxin, are more restricted in the species that can be intoxicated. Some bacterial toxins, such as pertussis toxin, can intoxicate numerous cell types, whereas other exotoxins, such as the clostridial neurotoxins, show a specific affinity and intoxicate only cells of neuronal origin. Bacterial exotoxins catalyze specific post-translational modifications of host cell components, such as the ADP-ribosylation reaction catalyzed by diphtheria toxin or the deamidation reaction catalyzed by the cytotoxic necrotizing factor of *Escherichia coli*. These chemical modifications may either inhibit or stimulate the normal action of the target molecule to yield a clinical pathology. Bacterial exotoxins possess an AB structure - function organization, in which the A domain comprises the catalytic domain and the B domain comprises the receptor-binding domain and the translocation domain. The translocation domain is responsible for the delivery of the catalytic A domain into an intracellular compartment of the host cell.

Many bacterial exotoxins can be chemically modified to toxoids that no longer express cytotoxicity, but retain immunogenicity. Bacterial toxins can also be genetically engineered to toxoids, which may lead to a wider range of vaccine products. Exotoxins have also been used as therapeutic agents to correct various human disorders, including the treatment of muscle spasms by botulinum toxin. Nontoxic forms of exotoxins have been used as carriers for the delivery of heterologous antigens to elicit an immune response

and as agents in the development of cell-specific chemotherapy. In addition, bacterial toxins have been used as research tools to assist in defining various eukaryotic metabolic pathways, such as G-protein-mediated signal transduction.

Classification of Exotoxins

Exotoxins are soluble proteins produced by microorganisms which can enter a host cell and catalyze the covalent modification of a cellular component(s) to alter host-cell physiology. The term 'host cell' refers to either vertebrate cells or cells of lower eukaryotes, such as protozoa because some bacterial exotoxins intoxicate a broad range of host cells. The recognition that some pathogenic bacteria produced soluble components capable of producing the pathology associated with a particular disease was determined in the late nineteenth century. Roux and Yersin observed that culture filtrates of *Corynebacterium diphtheriae* were lethal in animal models and that the pathology elicited by the culture filtrate was similar to that observed during the infection by the bacterium. Subsequent studies isolated a protein, diphtheria toxin, from the toxic culture filtrates and showed that the administration of purified diphtheria toxin into animals was sufficient to elicit the pathology ascribed to diphtheria. Diphtheria toxin is a prototype exotoxin and has been used to identify many of the biochemical and molecular properties of bacterial exotoxins.

The ability of a bacterial pathogen to cause disease frequently requires the production of exotoxins, but the mere ability to produce a toxin is not sufficient to cause disease. Cholera toxin is the principal virulence factor of *Vibrio cholerae*. Administration of micrograms of purified cholera toxin to human volunteers elicits a diarrheal disease that mimics the magnitude of the natural infection. Nonetheless, nonvirulent, toxin-producing strains of *V. cholerae* have been isolated and shown to lack specific biological properties, such as motility or chemotaxis. Similarly, although anthrax toxin is the principal toxic component of *Bacillus anthracis*, nonvirulent toxin-producing strains of *B. anthracis* have been isolated and shown to lack the production of a poly-glutamic acid capsule. In contrast, the botulinum neurotoxins can be ingested preformed in contaminated food and elicit the pathology of botulism; food poisoning by the botulinum neurotoxins is an intoxication rather than an infection.

Bacterial exotoxins are classified according to their mechanisms of action. The covalent modifications of host-cell components that are catalyzed by bacterial exotoxins include ADP-ribosylation, deamidation, depurination, proteolysis, and glucosylation (Table 1). Most cellular targets of bacterial exotoxins are proteins, although there are exceptions such as shiga toxin, which catalyzes the deadenylation of ribosomal RNA. In addition to exotoxins, there are several other classes of toxins that are produced by pathogenic bacteria, such as pore-forming toxins, type III-VI secreted cytotoxins, heat-stable enterotoxins, and superantigens. Each of these toxins fails to perform one of the properties associated with exotoxins. The pore-forming toxins are not catalytic in their action, but instead disrupt cell physiology through the formation of pores in the host-cell plasma membrane. The type III-secreted cytotoxins cannot enter host cells as soluble proteins, but instead are injected directly into the host cell by the type III secretion apparatus of a host-cell bound bacterium. The heat-stable enterotoxins and superantigens do not enter the intracellular compartment of the host cell, but elicit host-cell responses by triggering signal-transduction pathways upon binding to the host-cell membrane or by complexing host cells, respectively. In this article, initial emphasis will be placed on the molecular properties of bacterial exotoxins, with a subsequent description of the general properties of pore-forming toxins, type III-secreted cytotoxins, heat-stable enterotoxins, and superantigens.

The pathology elicited by a specific exotoxin results from the catalytic covalent modification of a specific host-cell component. Although diphtheria toxin and cholera toxin are both bacterial ADP-ribosylating exotoxins, the pathogenesis elicited by each exotoxin is unique. This is due to the fact that diphtheria toxin ADP-ribosylates elongation factor-2, resulting in the inhibition of protein synthesis and subsequent cell death, whereas cholera toxin ADP-ribosylates the G_s component of the heterotrimeric protein, which stimulates the activity of host adenylate cyclase. This stimulation of adenylate cyclase elevates intracellular cAMP, which triggers the secretion of electrolytes and H_2O from the cell, resulting in the clinical manifestations of cholera.

General Properties of Exotoxins

Genetic Organization of Exotoxins

The genes encoding bacterial exotoxins may be located on the chromosome or located on an extrachromosomal element, such as a plasmid or a bacteriophage. Elegant experiments characterizing diphtheria toxin showed that the gene encoding this exotoxin was located within the genome of the lysogenic-phage. Although both nonlysogenic and lysogenic strains of *C. diphtheriae* could establish local upper-respiratory-tract infection, only strains of *C. diphtheriae* lysogenized with the lysogenic beta-phage that encoded diphtheria toxin were capable of eliciting systemic disease. This established a fundamental property for the pathology elicited by bacteria that produce exotoxins; bacteria establish a localized infection and subsequently produce an exotoxin, which is responsible for pathology distanced to the site of infection.

Most exotoxins are produced only during specific stages of growth with the molecular basis for the regulation of toxin expression varying with each bacterium. This differential expression often reflects a complex regulation of transcription, including responses to environmental conditions, such as iron. Multi-subunit toxins are often organized in operons to allow the coordinate expression of their subunit components.

Table 1 Properties of Representative Bacterial Exotoxins.

Modification	Exotoxin	Bacterium	AB	Target	Contribution to pathogenesis
ADP-ribosylation	Diphtheria toxin	<i>C. diphtheriae</i>	AB	Elongation factor-2	Inhibition of protein synthesis
	Exotoxin A	<i>P. aeruginosa</i>	AB	Elongation factor-2	Inhibition of protein synthesis
	Cholera toxin	<i>V. cholerae</i>	AB5	Gs α	Inhibition of GTPase activity
	Heat-labile enterotoxin	<i>E. coli</i>	AB5	Gs α	Inhibition of GTPase activity
	Pertussis toxin	<i>B. pertussis</i>	AB5	Gi α	Uncouple signal transduction
	C2 toxin	<i>C. botulinum</i>	A-B	actin	Actin depolymerization
	ExoS	<i>P. aeruginosa</i>	A (type III delivered)	Multiple targets including Ras	Uncoupling of Ras signal transduction
	ExoT	<i>P. aeruginosa</i>	A (type III delivered)	Crk	Uncoupling of Rac signal transduction
	SpvB	<i>Salmonella</i>	A (type III delivered)	Actin	Disruption of the Actin cytoskeleton
Glucosylation	Lethal toxin	<i>C. sordelli</i>	AB	Ras	Inhibition of effector interactions
	Toxin A and B	<i>C. difficile</i>	AB	RhoA	Inhibition of Rho signaling
Endoprotease	Lethal toxin (Anthrax toxin)	<i>B. anthracis</i>	A-B	MAP kinase	Cell death
	Botulinum toxin (A–G)	<i>C. botulinum</i>	AB	SNARE proteins	Inhibition of vesicle fusion in neurons (flaccid paralysis)
	Tetanus toxin	<i>C. tetani</i>	AB	Vesicle Associated Membrane Protein (VAMP)	Inhibition of vesicle fusion in neurons (spastic paralysis)
				RhoA	Stimulation of RhoA
Deamidation	Cytotoxic Necrotizing Factor	<i>E. coli</i>	AB	RhoA	Stimulation of RhoA
Deadenylation	Shiga toxin	<i>Shigella</i> spp.	AB5	28S ribosome	Inhibition of protein synthesis
	Verotoxin	<i>E. coli</i>	AB5	28S RNA	Inhibition of protein synthesis
Adenylate cyclase	Adenylate cyclase toxin	<i>B. pertussis</i>	AB	cAMP production	Uncouple cell signaling
	Edema Toxin (Anthrax toxin)	<i>B. anthracis</i>	A-B	cAMP production	Uncouple cell signaling
	ExoY	<i>P. aeruginosa</i>	A (type III delivered)	cAMP production	Uncouple cell signaling
RhoGAP	SptP	<i>Salmonella</i> spp.	A (type III delivered)	Inhibition of RhoGTPase function	Inhibition of phagocytosis
	YopE	<i>Yersinia</i>	A (type III delivered)	Inhibition of RhoGTPase function	Inhibition of phagocytosis
	ExoS	<i>P. aeruginosa</i>	A (type III delivered)	Inhibition of RhoGTPase function	Inhibition of phagocytosis

Secretion of Exotoxins from the Bacterium

Most bacteria secrete exotoxins across the cell membrane by the type II secretion pathway. The secretion of exotoxins by the type II secretion pathway was predicted by the determination that the amino terminus of mature exotoxins had undergone proteolysis relative to the predicted amino acid sequence derived from the gene sequence encoding the exotoxin. Type II secretion is also called the general secretion pathway. Type II secretion involves the coordinate translation and secretion of a nascent polypeptide across the cell membrane. During the translation of the mRNA that encodes a type II-secreted protein, the amino-terminal leader sequence of the nascent polypeptide targets to and is secreted across the cell membrane. After secretion across the cell membrane, the nascent protein folds into its native conformation and the leader sequence is cleaved by a periplasmic peptidase to yield a mature exotoxin.

Some Gram-negative bacteria export the assembled exotoxin from the periplasm into the external environment via a complex export apparatus. While the heat-labile enterotoxin of *Escherichia coli* remains localized within the periplasmic space, *V. cholerae* and *Bordetella pertussis* assemble their respective exotoxins, cholera toxin and pertussis toxin, within the periplasm and then transport the mature exotoxin into the external environment. Although the multiple protein components of the export apparatus have been identified, the exact mechanism for export across the outer membrane remains to be resolved.

Bacteria Produce and Secrete Exotoxins as Proenzymes

Although one property of a bacterial exotoxin is the ability to intoxicate sensitive cells, early biochemical studies observed that, *in vitro*, many bacterial exotoxins possessed little intrinsic catalytic activity. These perplexing observations were resolved with the determination that bacteria produce and secrete exotoxins as proenzymes, which must be activated (processed) to express catalytic activity *in vitro*. The observed requirements for *in vitro* activation reflect the activation steps of the exotoxin *in vivo*. For example, an exotoxin may require specific conditions for activation, including proteolysis, disulfide-bond reduction, or association with a nucleotide, cofactor, or a eukaryotic accessory protein. Some activation processes result in the release of the catalytic A domain from

Figure 1 Bacterial exotoxins are produced as proenzymes. (Upper panel) Most bacterial exotoxins are produced as proenzymes that undergo processing to express catalytic activity. The sequential processing of botulinum toxin involves protein cleavage between the catalytic **A** domain (Red) and the Translocation (Green) and Receptor Binding (Yellow) **B** domain. The **A** and **B** domains are connected by a disulfide bond, which is reduced as the **A** domain is translocated into the host cytoplasm by agents such as reduced glutathione. (Lower panel) A ribbon diagram of botulinum neurotoxin is shown (Protein Data Bank # 3BTA). The catalytic **A** domain (Red) is linked to **B** domain, which includes the Translocation domain (Green) and the Receptor Binding domain (Yellow).

the **B** domain, whereas other activation processes appear to result in a conformational change rendering the catalytic **A** domain active. Some exotoxins require sequential activation steps. Diphtheria toxin is activated by limited proteolysis, followed by disulfide-bond reduction (Figure 1).

The determination of the activation mechanism of exotoxins often provides insight into several physiological pathways of host cells. The eukaryotic protein ARF (ADP-ribosylation factor), which activates cholera toxin *in vitro*, was subsequently shown to play a central role in vesicle formation within the eukaryotic cell. The ability of a host-cell extract to activate cholera toxin is often used as a sign of the presence of ARF. Cholera toxin is activated through a series of steps where the catalytic domain of the toxin is cleaved into an A1 and A2 fragment. The A1 fragment binds ARF which activates the protein to ADP-ribosylate the alpha subunit of the heterotrimeric G_s protein to uncouple cAMP regulation within the host cell. Characterization of the mechanisms that pertussis toxin and cholera toxin use to intoxicate eukaryotic cells provided insight into the pathways for eukaryotic G protein-mediated signal transduction. The ability of pertussis toxin to inhibit the action of a ligand in a signal-transduction pathway is often used to implicate a role for G proteins in that signaling pathway.

AB Structure-Function Properties of Exotoxins

Most bacterial exotoxins possess **AB** structure-function properties (Figure 2). The **A** domain is the catalytic domain, whereas the **B** domain includes the translocation and binding domains of the exotoxin. Exotoxins are organized into one of several general types of **AB** organization. The simplest **AB** organization is represented by diphtheria toxin, where the **A** domain and **B** domain are contained in a single protein. Diphtheria toxin is the prototype for this class of **AB** exotoxin. Diphtheria toxin is a 535-amino-acid

Figure 2 Bacterial exotoxins possess **AB** structure-function organization. There are three general **AB** organizations of bacterial exotoxins. The **A** domain (Red) represents the catalytic domain whereas the **B** domain comprises the translocation and receptor-binding domains (Yellow). **AB5** is represented by cholera toxin of *V. cholerae*, which is composed of six noncovalently associated proteins (PDB: 1XTC). **AB** is represented by diphtheria toxin of *Corynebacterium diphtheriae*, in which the **A** and **B** domain are included in a single protein (PDB: 1MDT). **A-B** is represented by protective antigen and lethal factor from anthrax toxin of *Bacillus anthracis*, which is composed of two non-associated proteins; the two proteins associate after the binding and processing of the **B** component on the host-cell membrane (PDB: 1ACC and 1JKY).

protein in which the amino terminus constitutes the ADP-ribosyltransferase domain and the carboxyl terminus comprises the translocation domain and receptor-binding domain. The AB₅ exotoxins are composed of six proteins that are noncovalently associated as an oligomer. Cholera toxin is the prototype for the AB₅ exotoxin. The A domain of cholera toxin constitutes the ADP-ribosyltransferase domain, whereas the B₅ domain is composed of five identical proteins, forming a pentamer, which is organized into a ring structure on which the A domain is positioned. The five proteins that make up the B domain may be identical, as is the case for cholera toxin and the heat-labile enterotoxin of *E. coli*, or may be an oligomer of different proteins that form a non-symmetrical ring structure, as observed with the B domain of pertussis toxin.

The third class of AB exotoxin is composed of proteins that are not associated in solution, but where the A and B domains associate following the binding and oligomerization of the B domain on the host cell. C2 toxin is an example of this class of A-B exotoxin. C2 toxin is a bipartite exotoxin composed of a protein that encodes the catalytic A domain and a separate protein that encodes the B domain. C2 toxin A domain ADP-ribosylates actin. The B domain of C2 toxin binds to sensitive cells, is nicked by a eukaryotic protease, and the nicked B domain oligomerizes and is then capable of binding the A domain protein. Anthrax toxin is a major virulence factor of *Bacillus anthracis*. Anthrax toxin is organized as an AB exotoxin that is composed of two unique A domains (edema factor, an adenylate cyclase, and lethal factor, a zinc protease) and a B domain (termed the protective antigen) which are not associated in solution. The A domains associate with the B domain subsequent to the binding and oligomerization of the B domain on the surface of sensitive host cells. Recent studies observed that three A domains can bind to each heptameric B domain on the host cell surface.

The B domain possesses two specific functions, receptor binding and translocation capacity. Each exotoxin uses a unique host-cell surface component as a receptor. The host cell surface receptor for an exotoxin may be a specific molecule or a non-specific group of molecules. For example, the cell surface receptor for cholera toxin is the ganglioside GM1, and the cell surface receptor for diphtheria toxin is the epidermal growth factor precursor. In contrast, the binding of pertussis toxin is less specific, as pertussis toxin binds numerous cell surface proteins. The ability to bind a cell surface receptor is an absolute requirement for an exotoxin to intoxicate a host cell, as the deletion of the receptor-binding domain renders the exotoxin noncytotoxic. After binding to the cell surface, some exotoxins are proteolytically processed or are processed during intracellular endosome transport.

The second function of the B domain includes translocation capacity, which is responsible for the delivery of the A domain across the cell membrane. The presence of a translocation domain was predicted from early structure-function studies of diphtheria toxin, which showed that in addition to the catalytic domain and receptor-binding domain, a third function was required for the efficient expression of cytotoxicity. This third function was subsequently shown to correspond to a region of diphtheria toxin that had the propensity to interact with membranes. The crystal structure of diphtheria toxin revealed the presence of three distinct domains, representing the catalytic, translocation, and receptor-binding domains.

Exotoxins Enter Host Cells via Distinct Pathways

Although A domain translocation is one of the least understood aspects of the intoxication process of exotoxins, there are several general themes that are involved in translocation of the A domain across the cell membrane. One translocation mechanism uses a pH gradient within the endosome to stimulate protein conformational changes in the B domain, making the B domain competent to interact with the membrane of the endosome. After insertion into the endosome membrane, the B domain generates a pore that is involved in the translocation of the A domain across the vesicle membrane in an unfolded form. After the translocation across the endosome membrane, the A domain refolds to its native conformation. Upon translocation of the A domain across the endosome membrane, reduced glutathione may reduce the disulfide that connects the A domain with the B domain, and release the A domain into the cytoplasm. The potency and catalytic potential of exotoxins was demonstrated by the observation that the introduction of one molecule of the catalytic domain of diphtheria toxin into the intracellular cytoplasm was sufficient to inhibit host-cell protein synthesis, resulting in cell death. Recent studies on the translocation process of anthrax toxin support the direct translocation of the A domain through a stable, gated channel formed by the heptameric B domain.

Other toxins, such as cholera toxin and exotoxin A of *Pseudomonas aeruginosa*, use retrograde transport to enter the interior regions of the cell. Movement occurs through retrograde transport of the endosome to the Golgi apparatus and ultimately to the endoplasmic reticulum. Many exotoxins that are ultimately delivered to the endoplasmic reticulum possess a KDEL (Lys-Asp-Glu-Leu)-like retention signal sequence on their carboxyl terminus. Studies with chimeric proteins have shown that the introduction of a KDEL retention sequence is sufficient to retrograde transport a protein from the endosome to the endoplasmic reticulum. Thus, there is physiological precedence for the use of the KDEL sequence to retrograde transport exotoxins toward the endoplasmic reticulum. The host mechanism that recognizes unfolded host proteins also translocates the A domain from the lumen of the endoplasmic reticulum into the host cell cytosol.

Covalent Modification of Host-Cell Components by Exotoxins

Exotoxins use several unique mechanisms to covalently modify host-cell components. The major classes of reactions are the covalent addition of a chemical group to the target protein, the cleavage of a chemical group from a target protein, or the endoproteolytic cleavage of a peptide bond of the target protein.

The ADP-ribosylation of host proteins is the prototypical mechanism of action of bacterial exotoxins. Numerous bacterial exotoxins catalyze the ADP-ribosylation of specific host proteins and elicit physiological changes. In the ADP-ribosylation reaction,

exotoxins use the oxidized form of nicotinamide adenine dinucleotide (NAD) as the substrate, and transfer the ADP-ribose portion of NAD to a specific amino acid via an *N*-glycosidic linkage of ADP-ribose onto the host target protein. The specific type of amino acid that is ADP-ribosylated within the target protein varies with the specific exotoxin. Diphtheria toxin ADP-ribosylates elongation factor-2 on a post-translationally modified histidine residue called diphthamide. ADP-ribosylated elongation factor-2 is unable to perform its translocation of nascent polypeptides in the ribosome, which results in the inhibition of protein synthesis and subsequent cell death. In contrast cholera toxin ADP-ribosylates the G_s component of a heterotrimeric G protein. ADP-ribosylated G_s is locked in an active conformation, which stimulates host adenylate cyclase and the subsequent elevation of intracellular cAMP. Thus, ADP-ribosylation may either activate or inhibit the activity of the target protein. Deamidation of Gln63 on RhoA by *E. coli* cytotoxic necrotizing factor (CNF) results in a constitutively active RhoA protein. Note that although most host targets for exotoxins are proteins, Shiga toxin catalyzes the deadenylation of a specific adenine on 28S RNA.

Recall that each exotoxin modifies a specific host-cell component, which is responsible for the specific pathology elicited by that exotoxin. Although there are no absolute rules for the types of proteins targeted for covalent modification, the most frequent targets are nucleotide-binding proteins that are involved in signal-transduction pathways, including both the heterotrimeric G-proteins and the small-molecular-weight GTP-binding proteins of the Ras superfamily.

Molecular and Structural Properties of Bacterial Exotoxins

Early biochemical studies provided significant advances in defining the structure-function properties of exotoxins, resolving many of the exotoxin mechanisms of action and developing the concept that exotoxins have AB organization. Molecular genetics and structural biology have extended these earlier studies and provide a more detailed understanding of the biochemical and molecular relationships among the exotoxins. The biochemical characterization of diphtheria toxin and exotoxin A (ETA) of *Pseudomonas aeruginosa* showed that these two exotoxins catalyzed kinetically identical reactions during the ADP-ribosylation of elongation factor-2. In addition, both diphtheria toxin and ETA possess an active site glutamic acid, which was subsequently shown to be a signature property of exotoxins that catalyze the ADP-ribosyltransferase reaction. These observations predicted that ADP-ribosylating exotoxins would possess considerable primary amino acid homology. Thus, the determination that the genes encoding diphtheria toxin and ETA shared little primary amino acid homology was unexpected. This paradox was resolved after the analysis of the three-dimensional structures of ETA and the heat-labile enterotoxin (LT) of *E. coli*. The three-dimensional structures of ETA and LT showed little similarity in their respective receptor-binding domains and translocation domains; however, the catalytic domains of ETA and LT, which are composed of seven discontinuous regions of each protein, could be superimposed on each other despite possessing homology at only three of the 43 amino acids. One of the homologous amino acids in ETA and LT was the signature active site glutamic acid. This was a remarkable finding because ETA and LT ADP-ribosylated different host target proteins and possessed different AB organization. A common theme has evolved for describing the structure-function properties of this family of bacterial exotoxins in which the ADP-ribosylating exotoxins possess a conserved three-dimensional structure in their active sites, despite the lack of primary amino acid homology. These findings provided a framework for the study of other classes of exotoxins produced by divergent groups of bacteria.

Conversion of Exotoxins into Toxoids

Chemical Detoxification of Bacterial Exotoxins

Shortly after the determination that toxic components were associated with bacterial pathogens, cell extracts or cell cultures of a pathogen were shown to be treated with chemical denaturants, such as formalin, to produce nontoxic-immunogens as vaccines to prevent disease upon subsequent exposure by that pathogen. In the case of diphtheria toxin and tetanus toxin, chemical modification with formalin produced toxoids that were used as subunit vaccines in large-scale immunizations. This resulted in a remarkable decrease in the incidence of both diphtheria and tetanus within the immunized population. In areas where these toxoids are not administered, diphtheria and tetanus remain clinically important diseases. In addition to formalin, other chemicals have been used to detoxify bacterial exotoxins, including glutaraldehyde and hydrogen peroxide. In contrast, the production of a chemical toxoid of other exotoxins, such as cholera toxin and pertussis toxin, has been more difficult because the treatment of these toxins with denaturants and reduced immunogenicity. Thus, there is a need to develop alternative strategies, such as genetically engineered and subunit vaccines, to eliminate the cytotoxicity of certain exotoxins without compromising their immunogenicity.

Genetic Detoxification and Subunit Vaccines of Bacterial Exotoxins

Developments in genetic engineering provide an opportunity to produce recombinant forms of bacterial exotoxins that possess greatly reduced toxicity, but retain immunogenicity. The use of genetic engineering to develop a toxoid of pertussis toxin has been successful. The whole-cell pertussis vaccine is composed of a chemically treated preparation of *Bordetella pertussis*, which is effective in the elicitation of a protective immune response after mass immunization. However, the whole-cell pertussis vaccine is acutely reactive when administered to children due to the crude nature of the vaccine that includes endotoxin. Recently a component pertussis vaccine has been developed that is administered with the diphtheria toxoid and tetanus toxoid (termed the DTaP vaccine)

which produces fewer adverse reactions in children than the whole cell pertussis vaccine. The reactivity of the acellular pertussis vaccine is so low that administration of this vaccine in adolescents and adults has been approved, an important development as adults are considered a primary carrier of *Bordetella pertussis*. Pertussis toxin, a primary virulence determinant of *B. pertussis*, is an exotoxin that ADP-ribosylates the G_i component of heterotrimeric G proteins and effectively uncouples signal transduction between the G protein-coupled receptor and the G protein. Genetically engineered forms of pertussis toxin have been produced that possess essentially no catalytic activity or cytotoxicity, but that maintain native conformation and elicit a protective immune response when used as an immunogen. These recombinant noncytotoxic forms of pertussis toxin have been engineered with multiple mutations in their active site, virtually eliminating the risk of reversion to a cytotoxic form. Similar strategies are being applied to other bacterial exotoxins with the goal of engineering acellular vaccine candidates.

Subunit vaccines represent another approach to developing safe and efficient vaccines. This strategy implies that a domain of the exotoxin can be identified that elicits a protective immune response against exotoxin challenge in the host. One example of a subunit vaccine is the development of a subunit vaccine against botulism. Botulism is a toxin-mediated disease elicited by botulinum toxin. Botulinum toxin is the most toxic protein for humans and is an AB toxin (Figure 2). Recent studies have shown that immunization with the C-terminal portion of the B domain stimulates a protective immune response against challenge by botulinum toxin. Recombinant forms of this C-terminal B domain have been produced in yeast and *Escherichia coli* and represent the next generation of botulism vaccines.

Therapeutic Applications of Exotoxins

One of the most exciting areas of bacterial exotoxin research has been the development of strategies to use exotoxins in therapeutic disciplines. Some therapies use the native cytotoxic form of the exotoxin. Other therapies use the A domain, which is conjugated to a heterologous binding component or to effector elements, respectively, to produce a chimeric molecule with directed properties.

Botulinum toxin and tetanus toxin (BT/TT) are single-chain proteins organized as AB exotoxins. The amino-terminal A domain of BT/TT express protease activity, cleaving SNARE proteins, which inhibits fusion of neurotransmitter vesicles to the plasma membrane of neurons. The carboxy-terminal B domain of BT/TT possesses motor neuron-specific receptor-binding activity that is unique for each exotoxin. BT enters synaptic vesicles of motor neurons and inhibits synaptic vesicle fusion at the neuromuscular junction, causing flaccid paralysis, while TT enters endosomes of motor neurons and retrograde traffics into the central nervous system to inhibit fusion of neurotransmitter vesicles to the plasma membrane of inhibitory neurons, yielding spastic paralysis. Thus, the specific intracellular trafficking of BT/TT is responsible for the clinical manifestation of each neurotoxin. BT is also a potent therapy of human diseases, and reduces muscle spasms associated with several clinical disorders, such as blepharospasm, an involuntary contraction of eye muscles. This application has expanded and BT is one of the most widely used therapeutic proteins in clinical medicine. The extreme potency of BT to humans has also made this a potential agent for malicious application.

Diphtheria toxin is a carrier of antigens to stimulate an immune response against several polysaccharide epitopes. One epitope is polyribitolphosphate, a component of the polysaccharide capsule of *Haemophilus influenzae* type b (Hib). Early attempts to elicit an effective immune response to purified Hib antigen resulted in a T-cell-independent immune response that did not yield an effective immune memory. A non-catalytic mutated diphtheria toxin, CRM197, is one of the protein carriers for the Hib epitope. Immunization with the CRM197-Hib conjugate yields a strong T-dependent immune response. Mass immunization with conjugate-Hib vaccines has dramatically reduced the number of cases of Hib in the immunized population.

Due to their potency, the catalytic A domain of exotoxins have been used in the construction of chimeric immunotoxins that target cancer cells. Early studies used conjugates that were composed of the A domain of the diphtheria toxin coupled to an antibody that recognized a cell surface-specific antigen. The A chain of the diphtheria toxin was used in the first generation of immunotoxins due to the A domains potency. Similar chimeras continue in development to treat specific human cancers.

Other Classes of Bacterial Toxins

Pore-Forming Toxins

The lack of a catalytic A domain differentiates the pore-forming toxins from exotoxins. Thus, the pathology associated with pore-forming toxins is due solely to the generation of a pore within the membrane of the host cell. Several bacterial pathogens produce pore-forming toxins, some of which are secreted by a type I secretion pathway. Unlike type II-secreted proteins, the amino terminus of type I-secreted proteins is not processed. Type I-secreted proteins possess a polyglycine signal sequence in the carboxyl terminus of the mature toxin to facilitate translocation. There are several classes of pore-forming toxins, including members of the hemolysin family of pore-forming toxins, the aerolysin family of pore-forming toxins, and the alpha-toxin of *Staphylococcus aureus*. Host-cell specificity differs among pore-forming toxins. The crystal structures of several of the pore-forming toxins have been determined. The molecular events generating a pore in the membrane of a host cell have been proposed for the aerolysin family of pore-forming toxins, where aerolysin is exported by *Aeromonas hydrophila* as a monomeric molecule, which binds to the host cell. A host protease nicks the monomer, which is then processed and subsequently oligomerizes. The oligomerized complex inserts into the membrane and generates a pore in the center of the complex, causing the release of the cytoplasmic components of the host cell.

Type III-Secreted Cytotoxins

The lack of a B domain differentiates the type III-secreted cytotoxins from exotoxins. Thus, the organization of the type III-secreted cytotoxins may be described as A domains that are specific effector proteins. Cell surface-bound bacteria transport type III-secreted cytotoxins directly into host cells. Type III-secreted proteins are unique from proteins secreted by either the type I or II secretion pathways, where the amino terminus of type III-secreted cytotoxins is not processed and the carboxy terminus does not possess a poly-glycine motif. Although progress has been made in establishing the components of the type III secretion apparatus, the mechanism for the delivery of type III-secreted proteins across the host-cell membrane remains to be resolved. Numerous bacteria possess type III secretion pathways, including members of the genera *Escherichia*, *Pseudomonas*, *Shigella*, *Salmonella*, and *Yersinia*. Cytotoxicity elicited by type III-secreted cytotoxins has an absolute requirement for the type III secretion apparatus of the bacterium, as purified forms of the cytotoxins are not toxic to host cells.

The A domains of type III-secreted cytotoxins possess several unique mechanisms of action, including the depolymerization of the actin cytoskeleton, phosphatase activity, ADP-ribosyltransferase activity, and the stimulation of apoptosis. Each type III secretion apparatus appears capable of delivering numerous type III-secreted proteins into the host cell. Recent studies have identified additional secretion systems that bacteria use to translocate proteins across the bacterial cell envelope. The type IV secretion system utilizes an apparatus related to the apparatus for DNA transfer between bacteria. The type IV secretion apparatus of *B. pertussis* transfers pertussis toxin from the periplasm across the cell envelope and into the extracellular environment, while the type IV secretion apparatus of *Agrobacterium tumefaciens* injects effector molecules directly into the host cells. The type V secretion system is an autotransporter system where a protein is composed of a catalytic domain that is transported across the bacterial cell envelope by another component of the protein termed the autotransporter domain. There are numerous type V secreted proteins, with VacA, a virulence factor of *Helicobacter pylori*, one of the most noted examples of a type V secreted protein. The type VI secretion system has been described best in *P. aeruginosa* and involves two protein families, Hcp, which forms nanotubes on the bacterial surface, and VgrG, which form trimers on the bacterial cell surface. Both proteins pierce membranes and transport proteins from the bacterial cell.

Heat-Stable Enterotoxins

The inability of the heat-stable enterotoxins to enter the host cell or possess catalytic activity differentiates the heat-stable enterotoxins from exotoxins. Several genera of bacteria produce heat-stable enterotoxins, including *Escherichia* and *Yersinia*. The heat-stable enterotoxin a (STa) of *E. coli* is the prototype toxin. *E. coli* secretes STa into the periplasm as a 72 amino-acid precursor, where three intramolecular disulfide bonds form and help process STa into a 53 amino-acid peptide. The 53 amino-acid peptide is exported into the environment, where a second proteolytic cleavage results in the production of an 18 or 19 amino-acid mature STa molecule. The mature STa binds a protein receptor on the surface of epithelial cells, which stimulates an increase in the intracellular concentrations of cGMP. The intracellular increase in cGMP stimulates chloride and H₂O secretion, resulting in diarrhea.

Superantigens

The inability of superantigens to enter the host cell or possess catalytic activity differentiates the superantigens from exotoxins. Superantigens are soluble proteins of approximately 30-kDa secreted by both *Streptococcus* and *Staphylococcus*. The superantigens bind to a component of the major histocompatibility complex of T lymphocytes through an antigen-independent mechanism, which stimulates binding of the T-cell receptor via an antigen-independent mechanism leading to the proliferation of a large subset of T lymphocytes, and the production of a pro-inflammatory immune response. The superantigens are especially potent toxins.

Glossary

Autotroph An organism that obtains its carbon by fixing carbon dioxide, bicarbonate or other C1 compound.

Chemolithotroph A prokaryote that uses an inorganic energy source and fixes carbon dioxide.

Heterotroph An organism that obtains both its carbon and energy from an organic source.

Phototroph An organism that uses solar energy.

Snotites Small gelatinous growths of micro-organisms that grow suspended from the roofs of underground mines and caves.

Abbreviations

AMD	Acid mine drainage
ARD	Acid rock drainage
C1 compounds	Organic compounds containing only one carbon atom
Ci	Inorganic carbon
EPS	Extracellular polymeric substances
LTSEM	Low temperature scanning electron microscopy
Pi	Inorganic phosphorus
PCS	Phytochelatin synthase
SEM	Scanning electron microscopy
SEM-BSE	Scanning electron microscopy combined with analysis of back scattered electrons
16S rRNA	Small sub-unit fraction of ribosomal ribonucleic acid

Defining Statement

This article gives an overview of the nature of extremely acidic environments and of the biodiversity of prokaryotic and eukaryotic micro-organisms found within them. How acidophiles interact with each other in both positive and negative fashions are described and the microbial ecology of some of the most widely studied extremely acidic environments on our planet is discussed. The importance of acidophilic micro-organisms in existing and emerging biotechnologies is highlighted throughout the article.

Nature and Origin of Extremely Acidic Environments

Marine waters constitute the largest biome on planet earth. The dominant bicarbonate buffer dictates that sea water is mostly moderately alkaline (pH 8.2–8.4), though more alkaline (e.g., at the Lost City hydrothermal field in the mid-Atlantic ridge) and acidic waters (e.g., in the vicinities of black smoker hydrothermal vents) can be found in small scale and micro-niches. Terrestrial environments (soils, fresh waters and brackish waters) have greater potential for extremes of pH to develop and become established for protracted periods. Acidic mineral soils and peatlands are widespread where bedrocks are non-basic (granitic etc.) and where precipitation exceeds evapo-transpiration potentials. However, with the notable exception of acid sulfate soils, these rarely develop pH values <4.2 (mineral soils) or <3.0 (acidic peats). The dominant acids here are aliphatic and aromatic organic acids, and they tend to have pK_a values that are considerably larger than “strong” mineral acids. For example, the pK_a values of acetic and benzoic acids are 4.75 and 4.2, respectively, while those of hydrochloric and nitric acids are both <0. It follows that biological (or abiotic) processes that generate strong mineral acids have far greater potential to result in the formation of very low pH environments than those, such as fermentation, that produce organic acids (which themselves are susceptible to being degraded). Biological generation of mineral acids other than sulfuric acid are, however, rare. Gastric juices produced by mammalian stomachs have pH values of 1.5–3.5, due to their content of hydrochloric acid. Nitrification (dissimilatory oxidation of ammonium and nitrite) generates nitrate, rather than nitric acid, since the vast majority of nitrifying microorganisms are pH sensitive and the process can therefore become self-limiting. In contrast, while many bacteria and archaea that oxidize elemental sulfur and reduced sulfur oxy-anions are also acid-sensitive (e.g., lower limits of ~pH 5 for some *Thiobacillus* spp. and ~pH 3.0 for *Thiomonas* spp.) others are far more tolerant of low pH, and are among the most extremely acidophilic of all known life-forms.

Microbiological generation of sulfuric acid by coupling the oxidation of elemental sulfur (S^0) to the reduction of oxygen (aerobic oxidation) is represented by Eq. (1):

Sulfuric acid has two pK_a values (-2.8 and $+1.9$) and as pH falls below ~ 2.0 the bisulfate (HSO_4^-) anion becomes increasingly relatively abundant and one, rather than two, hydronium ions are generated for each sulfur oxidized, which in turn slows down environment acidification, at least if quantified solely by pH measurements. These reactions can be seen in solfatara fields which are widely distributed in volcanic and geothermal areas (Fig. 1). Sulfur dioxide (SO_2) and hydrogen sulfide (H_2S) are important components of volcanic gases and can react together to generate elemental sulfur (Eq. 2),

or dissolve in water (both are fairly soluble gases) and be subjected again to microbiological oxidation, generating sulfuric acid. Some acidophilic bacteria are also able to oxidize zero-valent (S^0) and reduced sulfur in the absence of oxygen using iron (III) (ferric iron) as an alternative electron acceptor. As shown in Eq. (3) this actually generates considerably more acidity than does aerobic oxidation of sulfur:

Sulfur is one of the more abundant elements present in the earth's crust, accounting for 0.05% of the lithosphere on a weight basis, and can exist in any of nine oxidation states, varying from -2 to $+6$. It occurs in oxidized minerals such as gypsum

Fig. 1 (a) Elemental sulfur forming from gases venting the Soufriere Hills volcano on Montserrat, West Indies; (b) an acidic geothermal area (Norris geyser basin) in Yellowstone National Park, Wyoming; (c) a sulfur-rich hot spring in São Miguel, Azores.

(CaSO₄·2H₂O) and baryte (BaSO₄) in both of which sulfur has an oxidation state of +6. However, from the perspective of extremely acidic environments, the most important are reduced sulfide minerals where sulfur occurs in oxidation states of 0, −1 or −2. The most abundant, and in environmental terms, significant sulfide mineral is pyrite (FeS₂; “fools’ gold”). This and other sulfide minerals can be formed in high or low temperature environments, provided that they are anoxic. They are among the hardest and most dense minerals known, but are susceptible to being destroyed when exposed to both water and an oxidizing agent. The latter may be (as with sulfur oxidation) either molecular oxygen or soluble ferric iron, and the process can be entirely abiotic. However, some specialized acidophilic prokaryotes have evolved to essentially tap into the free energy available from sulfide mineral oxidation and use this to fuel carbon (and in some cases nitrogen) fixation and other metabolic processes. To mediate this, they not only have genetic information that codes for proteins involved in the oxidation of iron (II) and/or reduced sulfur but also to allow them to withstand the extremely acidic external liquors in which they exist.

How extremely acidic environments may form as a consequence of microbiological sulfide mineral oxidation can be understood by considering pyrite. This mineral degrades relatively slowly even in highly acidic solutions. It is, however, readily oxidized by soluble ferric iron which (in the absence of chelating agents such as oxalic acid) exists in significant concentrations only in very acidic liquors (pH values below ~2.5). Six ferric iron ions are required to oxidize one “FeS₂” and are reduced to ferrous iron in the process, with the sulfur moiety being released initially as thiosulfate (equation 4):

This is an abiotic reaction that generates acid but does not require oxygen. However, unless the oxidant (ferric iron) is continuously inputted from an external source, the process comes to a halt except where, as in the vast majority of both natural and anthropogenic extremely acidic environment, species of acidophilic bacteria and archaea that are able to regenerate ferric iron are present, and oxygen is available for them to catalyze the oxidation reaction. Since spontaneous chemical oxidation of ferrous iron proceeds very slowly at low pH, these micro-organisms play a critical role in pyrite oxidation, and are regarded as the primary agents involved in the oxidative dissolution of sulfidic minerals at low pH. The thiosulfate generated in Eq. (4) is unstable in low pH liquors and transforms to elemental sulfur and a variety of sulfur oxy-anions, all of which can be oxidized by “secondary” microbial members of the consortium present, forming sulfuric acid, as described previously. Some or all of the ferric iron generated from pyrite oxidation can undergo mineralization reactions to form secondary oxidized minerals such as jarosites, schwertmannite or ferrihydrite. Eq. (5) depicts a situation where ferric iron is partially mineralized to form schwertmannite:

As can be seen, this reaction is strongly acid-generating, which limits the extent to which secondary mineralization to this particular ferric iron mineral can occur. The system also provides a strong pH buffer to acidic iron-rich water bodies, helping to maintain their pH often to within the range 2.2–2.8. This is seen in the most well-known and researched extremely acidic environment on planet Earth, the Rio Tinto in south-west Spain, which remains within this pH range for most of its 60 km length. Another important attribute that this pH buffer/mineralization system affords is the strong coloration of acidic iron-rich environments: soluble ferric iron (complexed by hydroxyl and sulfate ligands) imbues an amber to ruby-red color to waters while underlying ferric iron-rich sediments have pigmentation ranging from straw to orange to deep brown (referred to as “ochre” or “yellow boy” Fig. 2(a)).

In contrast to extremely acidic environments that derive from sulfur oxidation, most low pH environments associated with sulfide mineral oxidation are anthropogenic and not located in volcanic or geothermal areas. In some pristine areas, such as Greenland and Antarctica, natural exposures of iron-rich deposits overlying sulfidic bedrocks (gossans) can generate acidic run-off waters, though these are generally limited in the amount of acid (and soluble metals) they generate by the physical nature of the bedrock which limits its exposure to oxygen and water. In contrast, when deep-buried sulfidic rock strata are mined as ore bodies, haulage to the land surface followed by crushing and grinding (comminution) of the metal-rich fractions greatly increases the exposed surface areas of minerals and therefore their susceptibility to oxidative dissolution. Many of the most important base metals used by modern society occur either predominantly (e.g., copper and zinc) or extensively (e.g., nickel) as sulfide minerals in the lithosphere. While most of these target minerals are recovered from crushed ore by froth floatation, other sulfide minerals, such as pyrite, end up in fine-grain mineral wastes known as “tailings”. These are generally stored underwater in vast lagoons in order to limit oxygen ingress and the microbially-accelerated oxidative dissolution of reactive minerals, except in arid areas such as the Atacama desert. Even so, oxidation of pyrite and other sulfide minerals (which may contain highly noxious metals and metalloids such as cadmium and arsenic) in an on-going process, even in storage lagoons, particularly where water levels fluctuate, causing the generation of acidic, metal-rich waters which may accumulate within and eventually drain the site (Fig. 2(b)), and being the cause of more widespread environmental pollution. Waters of similar chemistries may also form within abandoned deep mines, in waste rock and spoilage dumps, at and around coal mines as well as metal mines and in the voids of closed and abandoned opencast mines (Fig. 2(c)). The latter become infilled, at different rates, with groundwater, forming pit lakes that typically are stratified with surface layers often being moderately or severely acidic. Waste waters associated with metal and coal mining (often referred to generically as “acid mine drainage”) have long been recognized as a major environmental threat to areas adjacent to, and sometimes distant from, abandoned mines. The causative agents of the formation of these metal-rich, acidic water bodies are again the specialized, mostly acidophilic, microbial consortia described above (and in more detail below) that exploit the opportunities given

Fig. 2 (a) The Rio Tintillo, an iron-rich extremely acidic river that flows through south-east Spain, showing the accumulation of secondary ferric iron minerals and terraces and the orange-red coloration typical of extremely acidic iron-rich water bodies; (b) a pit lake formed by the ingress of ground water into an abandoned opencast metal mine (San Telmo, Spain); (c) an acidic metal rich stream draining an abandoned copper mine in Avoca, Ireland.

to them in human activities inadvertently making accessible sulfide minerals from which they can indirectly obtain the energy they need to sustain their somewhat unusual life-styles.

Extremely Acidophilic Micro-Organisms

Although highly acidic and often metal-rich environments are toxic to most life-forms, a surprisingly large number of diverse organisms can thrive in some situations, though *bona fide* (metabolically-active) indigenous life-forms are microbial and mostly single-celled. Although some angiosperms have been observed to grow in highly acidic lakes, their root systems grow in sediments in which the pH is usually much higher than the water body itself. The axiom that as an environmental parameter (in this case, acidity) becomes more extreme, biodiversity declines holds true for both simple and complex life-forms. Research over the past 30 or so years has unveiled a large diversity of acidophilic microorganisms, which occur randomly throughout the “tree of life” in all three domains – Bacteria, Archaea and Eukarya – indicating that acidophily is a trait that has developed on many occasions during the evolution of life on planet Earth, rather than from a single adaptation event. As with other extremophiles, acidophiles tend to be specialized life-forms, and most extreme acidophiles are unable to grow in neutral pH environments. Another trait they have in common with most other extremophilic life-forms is that, while acidophiles that tolerate other physico-chemical extremes (e.g., very high temperatures or hyper-salinity) as well as extreme acidity do exist, these tend to be less acid-tolerant than those species that can tolerate extreme acidity alone. This is particularly noticeable among eukaryotic acidophiles. The biodiversities of extremely acidophilic prokaryotic and eukaryotic is described in the following sections.

Prokaryotic Extreme Acidophiles

Prokaryotes comprise Bacteria and Archaea. Although these are the most simple life-forms in terms of their morphologies (single celled organisms, occurring mostly as rods, spheres, filaments or vibrios), in terms of the physiological and metabolic potential they

(as a group) are vastly superior to eukaryotes. One reason for this is that prokaryotes have been resident on planet Earth for an estimated 3.8 billion years, while the first (single celled) ancestors of eukaryotes are thought to have emerged about 2.7 billion years ago.

The first extremely acidophilic micro-organism to be isolated and characterized (by Waksman and Joffe in 1921) was the sulfur-oxidizing bacterium, *Acidithiobacillus* (*At.*) *thiooxidans*, though it was referred to at the time as *Thiobacillus thiooxidans*. Some years later, another sulfur-oxidizing bacterium was isolated from water draining a coal mine that had the unique trait (at the time) of also being able to oxidize ferrous iron to ferric at very low pH. (*Acidi*)*thiobacillus ferrooxidans* has subsequently become the most well-studied of all acidophilic micro-organisms. It is now known, however, that many acidophilic bacteria that were previously considered to be strains of *At. ferrooxidans*, on the basis that they were aerobic straight rods that could oxidize both iron and sulfur, were probably other species which were unrecognized until relatively recently. Currently, the genus *Acidithiobacillus* comprises seven species, all of which (by definition) oxidize reduce sulfur and four of which (*At. ferrooxidans*, *At. ferridurans*, *At. ferrivorans* and *At. ferriphilus*) can also oxidize ferrous iron, and the genus will undoubtedly undergo further revision and expansion in future years. Both of the early *Acidithiobacillus* isolates (and all since) are autotrophic chemolithotrophs, i.e. they use inorganic electron donors and fix carbon dioxide. Such a metabolic life-style is highly appropriate in extremely acidic environments which tend to contain elevated concentrations of potential inorganic “energy sources” (electron donors, such as ferrous iron and reduced sulfur) but often low concentrations of dissolved organic carbon.

The major method by which single-celled prokaryotes generate ATP is by generating proton (hydronium ion) concentration gradients across their cell membranes, and then allowing controlled influx of protons through specific channels (ATPases). This is also the case for mitochondria in eukaryotic cells. On the face of it, therefore, acidophilic prokaryotes have an immediately available energy source as their cytoplasm has a typical pH values of around 6.5 while their external solutions are often in the pH range of 1.0–3.0 (i.e., differential proton concentrations of 4–6 orders of magnitude). The immediate energy source for acidophilic prokaryotes is this pre-existing proton gradient, though a major challenge to them is to prevent ingress of protons into their cytoplasm other than through defined channels. Obviously even tightly controlled influx of protons will ultimately lead to severe internal acidification and death, and with almost all electron donors used by these prokaryotes, they are faced with the challenge of pumping out protons against concentrations gradients that are immensely different to their neutrophilic counterparts. The single exception to this is ferrous iron, which is used as an electron donor by many species of chemolitho-autotrophic and chemolitho-heterotrophic acidophiles. In Gram-negative acidophiles, ferrous iron is oxidized within the periplasm (the space between the inner and outer membranes). This is necessary, as the ferric iron produced is highly insoluble in all but acidic liquors and would precipitate and accumulate inside bacteria and archaea if this was an intracellular reaction. The periplasm, however, has a similar pH to the bathing (external) acidic liquor, which facilitates the diffusion of the ferric iron waste product away from the cells. The electron captured from ferrous iron is transferred through the inner membrane, eventually being used to “neutralize” inflowing protons, forming, in combination with molecular oxygen, water (reaction (6)):

It should be noted that oxidation of ferrous iron consumes acidity, which can be considered as “de-energizing” these extreme environments, in contrast to reactions involving zero-valent sulfur (reaction (1)) or reduced sulfur oxy-anions which generate acidity and can therefore be considered to “re-energize” these environments.

There are various ways in which acidophilic prokaryotes can be, and have been, sub-categorized. Traditionally this has been on the basis of physiological traits, and this can be very useful, for example when considering their applications in biotechnologies. However, in more recent times categorizing acidophiles on the basis of their phylogenetic affiliations has become more commonplace.

Categorization Based on pH and Temperature Responses

The ability to tolerate elevated concentrations of protons (hydronium ions; H_3O^+) is obviously what defines an acidophile. While there is no official cut-off pH value that delineates whether an organism is or is not an acidophile, the generally accepted view is that, as a group, these can be divided into extreme acidophiles that have pH optima for growth at $\text{pH} < 3$, and moderate acidophiles that have pH optima of between 3 and 5. The term “hyper-acidophiles” has been proposed for the relatively few species that grow optimally below pH 1.0. Acid-tolerant organisms have pH growth optima above 5, though can also grow at lower pH values. As would be anticipated, the most extremely acidic environments have less potential biodiversity than those that are moderately acidic. The number of prokaryotes that are known to grow at $\text{pH} < 1$ is relatively small, and includes some Gram-positive bacteria (e.g., *Sulfobacillus* spp.), Gram-negative bacteria (e.g., *Leptospirillum* spp. and *At. thiooxidans*) and Archaea (e.g., *Ferroplasma* spp.) that oxidize iron and/or sulfur. The most acidophilic of all currently-known life forms is, however, a heterotrophic archaeon, *Picrophilus*. Two species are known, *P. oshimae* and *P. torridus*, both of which have optima pH for growth of ~ 0.7 , and grow in synthetic media poised and $\text{pH} \sim 0$. These hyper-acidophiles are also thermophilic, with optimum temperatures for growth at $\sim 60^\circ\text{C}$.

One of the most widely used methods to categorize acidophilic prokaryotes is on the basis of their temperature characteristics, i.e. their optimum temperatures for growth and range of temperatures within which they are active (Table 1). Three groups of acidophiles have often been recognized in this way: (i) Mesophiles, with temperature optima of $20\text{--}40^\circ\text{C}$; (ii) moderate

Table 1 Categorization of validated species of extremely acidophilic prokaryotic micro-organisms, based on growth temperature optima

		Electron donors			
Acidophile	Carbon assimilation	Fe ²⁺	ZVS/S oxy-anions	H ₂	Fe ³⁺ reduction*

thermophiles, with temperature optima of 40–60°C; (iii) extreme thermophiles, with temperature optima of 60–80°C. The term “thermo-tolerant” has also been used to describe those acidophiles, such as *L. ferriphilum*, that can grow above 40°C but not above 50°C, and also for those that are very active over a wide temperature range (e.g., 25 to >45°C in the case of *At. caldus*). While some acidophiles (*At. ferrivorans*, *Ferroplasma myxofaciens* and some strains of *Acidiphilium*) have been demonstrated to be active at very low (<5°C) temperatures, all of these have temperature optima well above 20°C, and are therefore psychro-tolerant rather than psychrophilic micro-organisms. At the other end of the temperature spectrum, the most thermophilic extreme acidophile known is the facultatively anaerobic sulfur-metabolizing archaeon *Acidianus infernus*, which has a growth temperature optimum of 90°C and a maximum of about 96°C. However, relatively few hyper-thermophilic acidophiles are known, and the fact that the maximum temperature for growth of an acidophile is about 25°C lower than that of the most thermophilic life-forms known (neutrophilic *Pyrolobus*-like archaea) is possibly a reflection of the difficulty that living organisms have when challenged by the dual stresses of extreme temperature and acidity.

As with neutrophilic prokaryotes, extremely thermophilic acidophiles are mostly Archaea while mesophiles are predominantly Bacteria. The majority of moderate thermo-acidophiles and thermo-tolerant acidophiles are also Bacteria, and mostly Gram-positives, while most known Gram-negative acidophilic bacteria grow best at below 40°C. There are exceptions to this general trend. Indeed, the most thermophilic acidophilic bacteria known - the sulfur-oxidizing autotroph *Hydrogenobaculum acidophilum*, which grows at up to 70°C, and the heterotroph *Acidicaldus organivorans*, which grows at up to 65°C - are both Gram-negative.

Categorization Based on Requirement for Molecular Oxygen

The majority of known acidophilic prokaryotes have been described, when first characterized, as obligate aerobes. More detailed examination has revealed that, in many cases, they can also grow in the absence of oxygen and are therefore facultative anaerobes. Of the various options that micro-organisms use for living in the absence of oxygen, by far the most widespread among acidophiles appears to be ferric iron respiration. This is understandable since iron, as both ferrous and ferric, is usually abundant in extremely acidic environments, particularly those originating from the oxidative dissolution of sulfide minerals. There is also a thermodynamic advantage to be gained from using ferric iron, in that the redox potential (E_h value) of the ferrous/ferric couple in acidic sulfate-rich waters is ca. +680–700 mV, a value which is not much below that of the oxygen/water couple (+840 mV at pH 7) and considerably more positive than alternative inorganic electron acceptors such as nitrate and sulfate. Most Bacteria (and the euryarchaeotes, *Ferropasma* and *Acidiplasma*) that can oxidize ferrous iron in the presence of molecular oxygen can also reduce ferric iron when oxygen is absent. Notable exceptions are species of *Leptospirillum*, though this is explained by the fact that these highly specialized bacteria have not been demonstrated to use an electron donor other than ferrous iron. Other acidophilic bacteria that also reduce ferric iron to ferrous are obligate heterotrophs, one of which (*Ferrimicrobium acidiphilum*) is also an iron-oxidizer, while others (*Acidiphilium*, *Acidocella* and *Acidobacterium* spp.) are not. Recently it has been shown that sulfur-oxidizing *At. caldus* and *At. thiooxidans* can reduce ferric iron when grown under aerobic conditions. The mechanism for this is indirect and not well understood, though it has been demonstrated that neither acidophile can grow via ferric iron respiration.

Sulfur respiration (the use of elemental sulfur as electron acceptor) is a widespread characteristic of acidophilic archaea: *Acidianus*, *Stygiolobus*, *Sulfurisphaera* (all thermo-acidophilic crenarchaeotes) and *Thermoplasma* (a moderately thermo-acidophilic euryarchaeote) can all grow anaerobically by reducing sulfur to hydrogen sulfide. *Acidianus* spp. and *Sulfurisphaera ohwakuensis* are both facultative anaerobes that couple the oxidation of hydrogen to the reduction of sulfur in anoxic environments, while *Stygiolobus azoricus* is an obligately anaerobic thermo-acidophile that can do the same. In contrast, both classified species of *Thermoplasma* (*Tp. acidophilum* and *Tp. volcanium*) are facultative anaerobes that couple the oxidation of organic carbon to the reduction of zero-valent sulfur. No extremely acidophilic sulfur- or sulfate-reducing bacteria (SRB), or sulfate-reducing archaea, have yet been isolated and characterized, though moderate acidophiles and acid-tolerant species, such as *Desulfosporosinus acididurans*, some of which are metabolically active at pH <3, have recently been described.

Clones of methanogenic archaea have also been identified in gene-libraries constructed from DNA extracted from some extremely acidic environments, but no extremely acidophilic methanogens are known. Likewise, no acetogenic acidophiles have been characterized, though this may be explained on the biotoxicity of acetic acid in low pH liquors. The general toxicity of aliphatic acids may also help account for the apparent absence of fermentative metabolism among extreme acidophiles, with the exception of the thermophilic archaeon *Acidilobus aceticus*, which can grow by fermenting starch to acetic acid. The scarceness of nitrate in most acidic environments, apart from those in the vicinity of rock blasting, and the fact that acidophiles are more sensitive to nitrate and nitrite than most other bacteria, are probably why nitrate respiration is apparently absent in these micro-organisms.

Categorization Based on Carbon Assimilation

Some extremely acidophilic prokaryotes fix CO₂, like green plants (obligate autotrophs), others have an absolute requirement for pre-fixed (organic) carbon (obligate heterotrophs), while a third group fix CO₂ but switch to assimilating organic carbon if and when this becomes available. The metabolic logic for the latter is obvious; CO₂-fixation is a highly energy-consuming process (e.g., the iron-oxidizing acidithiobacilli have been estimated to utilize most of the energy they obtain from oxidizing iron on this single process) and using pre-fixed carbon, assuming that it is readily incorporated and metabolized, avoids this expenditure of energy. Various terms have been used to describe such micro-organisms, which include some eukaryotic algae as well as some prokaryotic acidophiles, though the most appropriate (and least ambiguous) is to refer to them as facultative autotrophs.

Acidophilic autotrophic prokaryotes appear, either predominantly or exclusively, to use inorganic electron donors (iron, reduced sulfur and hydrogen) rather than solar energy, to sustain their growth. Cyanobacteria and green- and purple sulfur-bacteria that are found in higher pH environments appear not to occur (or at least be active) in extremely acidic environments. In some situations, chemolitho-autotrophs are the only primary producers present (e.g., in abandoned underground mines and acidic caves) yet, as evidenced by the scale of life that has been reported in some of these sites, their activities can underpin large accumulations of acidophilic biomass. Where solar energy is accessible however, they mostly take a more minor role in net primary production than acidophilic micro-algae.

Bacteria, in particular, are renowned as a collective group of micro-organisms for their abilities to degrade a multitude of small and large molecular weight organic compounds, including many synthetic materials. Acidophilic prokaryotes, on the other hand, appear to use a far more restricted range of monomeric organic substrates, and few polymeric materials. Simple sugars and alcohols

are utilized by many heterotrophic acidophiles, but small molecular weight aliphatic acids tend to be lethal to acidophiles when present in only micro-molar concentrations. The reason for this relates to the fact that these organic acids exist primarily as undissociated, lipophilic molecules in low pH liquors. These can freely permeate microbial membranes and accumulate in the circum-neutral pH cell interiors where they dissociate and cause intracellular acidification of the cytoplasm. Di- and tricarboxylic organic acids, such as citric acid, are not so toxic and are actually used as substrates by many heterotrophic acidophiles. Some organic acids, most notably glutamic acid, also serve as appropriate substrates for many acidophiles, though others (e.g., glycine) do not. Complex, nitrogen-rich organic substrates, such as yeast extract and tryptone, are also suitable substrates for isolating and cultivating many heterotrophic acidophiles, and supplementing defined organic growth media with, for example, yeast extract, often promotes growth of heterotrophic acidophilic bacteria and archaea. One of the few known examples of an acidophile being able to grow on an organic polymer is the archaeon *Acidilobus aceticus*, which grows anaerobically on starch, forming acetate as the main metabolic product.

Specialized and Generalist Acidophilic Prokaryotes

Acidophiles as a group are highly versatile, and are able to utilize a wide variety of energy sources (solar, and inorganic and organic chemicals), grow in the presence or complete absence of oxygen, and at temperatures of between 4°C and 96°C. However, individual species display very different degrees of metabolic versatility. Among the most specialized acidophiles are *Leptospirillum* spp. and *Ferroplasma myxofaciens*, all of which are known only to use a single electron donor (ferrous iron) to support their growth and, because of the high redox potential of the ferrous/ferric couple these bacteria have, by necessity, to use molecular oxygen as electron acceptor, restricting them to being metabolically active only in aerobic environments. *Leptospirillum* spp. and *Ferroplasma myxofaciens* are obligate autotrophs, and can also fix dinitrogen. Their metabolic limitations appear, however, to be compensated for by other physiological advantages that they have over other iron-oxidizing acidophiles. In the case of *Leptospirillum* spp., their greater affinity for ferrous iron and tolerance of extremely high concentrations of ferric iron and for growth in temperatures >40°C than, for example, the iron-oxidizing acidithiobacilli, enables them to out-compete the latter bacteria in many natural and anthropogenic environments, such as stirred tank bioreactors used to bioleach or bio-oxidize sulfide ores.

Species of the genus *Acidithiobacillus* are, in contrast, more generalist bacteria. Some can use a variety of inorganic electron donors (iron, sulfur and hydrogen) while others use a more limited range. Even within species, there may be differences in this regard. For example, only one strain of *At. ferroplasma* and one of *At. thiooxidans* have been found to use hydrogen as electron donor. While all iron-oxidizing acidithiobacilli have been confirmed to be facultative anaerobes, species, such as *At. thiooxidans*, that cannot oxidize iron do not grow under anoxic conditions.

The most generalist of all acidophiles are spore-forming Firmicutes of the genus *Sulfobacillus*, and to a lesser extent *Alicyclobacillus* and *Acidibacillus* spp.. *Sulfobacillus* are Gram-positive bacteria that can grow in aerobic or anaerobic environments, and are facultative autotrophs. They use a wide range of electron donors, including ferrous iron, hydrogen, zero-valent sulfur and reduced sulfur oxy-anions, and a variety of organic compounds (such as glucose and glycerol) as carbon sources and electron donors, though their capacities for heterotrophic growth are more limited than the more heterotrophically-inclined *Alicyclobacillus* spp..

Categorization of Acidophilic Prokaryotes on the Basis of Their Phylogenetic Affiliations

As elsewhere in (micro)biology, classification based on biomolecular signatures (mostly on comparative sequences of 16S/18S rRNA genes) has become the *prime facie* way of categorizing extremophilic prokaryotes. Acidophilic micro-organisms can be found apparently randomly distributed throughout the tree of life. This is particularly apparent for prokaryotic acidophiles within the domains Bacteria and Archaea.

Domain Bacteria. Many acidophilic bacteria are Gram-negative Proteobacteria, the largest of the bacterial phyla. The Alpha-proteobacteria includes three genera of extreme acidophiles: *Acidiphilium*, *Acidocella* and *Acidimonas*. All three are obligate heterotrophs, except (at present) for one species of *Acidiphilium* (*A. acidophilum*) which is a facultative autotroph which, like *Acidithiobacillus* spp., can use oxidation of zero-valent sulfur to fuel the fixation of carbon dioxide. Several other *Acidiphilium* spp. can also oxidize sulfur, though they require organic carbon. *Acidiphilium* spp. are also frequently found in tight association to iron-oxidizing *Acidithiobacillus*, possibly because they are the most acidophilic of the three genera. *Acidocella aromatica* is unusual (for an acidophile) in being able to grow on a range of aromatic compounds and aliphatic acids. *Acidimonas methanolica* (currently the only species of this genus) was named as such to reflect its growth on C₁ compounds, though this is something that is also characteristic of *Acidiphilium* spp.. In contrast, only one extreme acidophile is currently affiliated to the Betaproteobacteria, the iron-oxidizing autotroph *Ferroplasma myxofaciens*, which forms macroscopic “streamer-like” growths in flowing, acidic (pH >2) ferruginous waters, and also to the Gammaproteobacteria (the iron/sulfur-oxidizing autotroph *Acidiferrobacter thiooxydans*). Previous phylogenetic uncertainty regarding acidophiles of genus *Acidithiobacillus* (Table 1) was resolved by allocating these (and the closely related neutrophilic genus, *Thermithiobacillus*) to a new class within the Proteobacteria phylum, the Acidithiobacillia. Other Gram-negative extreme acidophiles are found within the deeply-branching bacterial phyla Nitrospirae, Aquificae and Verrucomicrobia. The most widely studied of these, primarily because of their importance in mineral processing biotechnologies, are *Leptospirillum* spp. (Nitrospirae), described above. *Hydrogenobaculum acidophilus* (Aquificae) grows autotrophically on hydrogen

at an optimum temperature of 65°C, while *Methylophilium infernorum* (Verrucomicrobia) is a methylotrophic acidophile that grows optimally at pH 2.0–2.5 and at 60°C.

Gram-positive extreme acidophiles currently fall within two phyla: Actinobacteria and Firmicutes. The Actinobacteria houses six described (though not all validated) species, most of which can both oxidize and reduce iron, though sulfur-oxidation is a relatively rare trait within this group. Species vary in both their temperature characteristics and morphologies, growing as mesophilic and moderately thermophilic cells that form single rods and long entwined filaments. Spore-forming Gram-positive extreme acidophiles (Firmicutes) comprise three genera: *Sulfobacillus*, *Alicyclobacillus* and *Acidibacillus*. *Sulfobacillus* spp. are described above. The first *Alicyclobacillus* spp. were moderate acidophiles that were isolated from pasteurized fruit juices, while more recent species and strains were isolated from mineral leaching environments, and catalyze the dissimilatory oxidation of ferrous iron and/or sulfur. Most recently, three species of the novel genus *Acidibacillus* have been described. These are obligately heterotrophic extreme acidophiles that oxidize iron (and some also oxidize sulfur) and which vary in their temperature characteristics. *Acidibacillus* have global distribution in a wide range of environments (e.g., geothermal sites, mine waste and sulfur deposits) and have been isolated from neutral pH as well as acidic sites.

Domain Archaea. Currently, there are six recognized genera of extreme acidophiles located within the archaeal phylum Euryarchaeota, all within the order *Thermoplasmatales*: *Ferroplasma*, *Acidiplasma*, *Thermoplasma*, *Picrophilus*, *Thermogymnomonas* and *Cuniculiplasma*. All of these are heterotrophic, though it has also been claimed that one (*Fp. acidiphilum*) can also fix inorganic carbon. Another notable feature is that some species lack cell walls, causing cells to have irregular and often variable morphologies. *Thermoplasma acidophilum* was the first extremely acidophilic heterotrophic prokaryote to be described, while *Picrophilus* spp. have the distinction of being the most acidophilic of all currently known life forms, with pH optima of ~0.7 and minima of <pH 0. *Ferroplasma* and *Acidiplasma* frequently occur in commercial biomining operations, though their precise roles here have yet to be elucidated. While both can oxidize ferrous iron (and thereby contribute, in theory, to accelerating the oxidative dissolution of metal-containing minerals) they are both scavengers of organic carbon (such as dead bacteria), and their relative numbers in bioleaching operations increase in response to the mortality of other bioleaching micro-organisms.

Extremely acidophilic crenarchaeotes are all thermophiles and members of the order *Sulfolobales*, and include the first extremely thermo-acidophilic archaeon to be characterized, *Sulfolobus acidocaldarius*. Some species, though not *S. acidocaldarius*, can oxidize reduced sulfur and one (*Sulfolobus metallicus*) can also grow chemolitho-autotrophically on ferrous iron. Other *Sulfolobales* (e.g., *Metallosphaera*, *Sulfurococcus* and *Acidianus* spp.) also oxidize sulfur and/or iron, and are thought to be important in high temperature (>60°C) mineral bio-processing operations. Some *Acidianus* spp. are able to use sulfur either as an electron donor under aerobic conditions, or as an electron acceptor (coupled to the reduction of hydrogen) under anaerobic conditions. Two other species of thermo-acidophilic archaea, *Sulfurisphaera ohwakuensis* and *Stygiolobus azoricus*, can also grow via sulfur respiration, generating H₂S.

Eukaryotic Extreme Acidophiles

The pioneering studies conducted by Thomas Brock on extremophiles in the hydrothermal vents of Yellowstone National Park focused on life in extreme environments of prokaryotes and their metabolisms. However, eukaryotic microbial life has also been observed in almost all extreme settings where there is a source of energy to sustain it, the only exceptions being high temperature environments (>70°C) and the deep subsurface biosphere. Eukaryotic organisms have been found to be highly adaptable, and molecular analysis of different extreme environments, including extremely low pH sites, has unveiled new protist genetic diversity. As is the case with prokaryotic acidophiles, representatives from multiple evolutionary eukaryotic lineages occur in low pH environments, suggesting that the ability to adapt to this environmental extreme is widespread. Which environmental parameters are most influential in determining eukaryotic microbial diversity patterns at pH extremes remains under-explored.

Diversity of Eukaryotic Acidophiles

Species belonging to the four main eukaryotic superclades, SAR supergroup (*Stramenopiles*, *Alveolates* and *Rhizaria*), *Excavata*, *Archaeplastida* and *Unikonta* have been described in extremely pH environments. Within *Stramenopiles*, diatoms from the genera *Pinnularia* are the most widespread, as well as *Alveolates* such as *Oxytricha* ciliate. Species related to the order *Cercomonas* are the main micro-organisms within the *Rhizaria*. Members of *Excavata* (heterotrophic flagellates) include species belonging to *Bodo* and *Ochromonas* genus as well as Euglenozoans such *Euglena mutabilis*. AMD-related *Archaeplastida* include phototrophic red (*Rhodophyceae*) and green algae (mainly *Chlorophyta*); these organisms depend on sunlight and are present in open-air systems. Additionally, *Heterolobosea* (amoebas) genera *Naegleria* and *Vahlkampffia*; *Rotifera* (i.e. *Cephalodella acidophila*); heliozoan (*Actinophrys*) and *Fungi* (*Opisthokonta*) complete the general set of eukaryotes found in acidic emplacements. The *Ascomycota* and *Basidiomycota* fungi are the primary eukaryotic members in sub-surface low-pH biofilms.

In acidic geothermal springs, the unicellular rhodophyte *Galdieria sulphuraria* (formerly *Cyanidium caldarium*), is often the dominant eukaryote worldwide. This moderate thermophile (35–56°C) may grow as a heterotroph in the absence of light (as may *Euglena*) and has been reported to grow at pH values around zero. Related *Galdieria* species can be found also in acidic AMD and ARDs since they are extremely tolerant to heavy metals being able to absorb high concentrations of them from the acidic water.

These eukaryotic microbial communities are distributed in extensive biofilms, formed mainly by photosynthetic species surrounded by an extracellular matrix. Microbial biofilms are organized multicellular systems with a structural and functional architecture which influences metabolic processes, response to nutrients, predation and other factors of the ecosystem. Thus, it has been suggested that biofilm structures generate micro-niches in which the environmental conditions are less stressful, thereby facilitating physiological activities that would not be feasible in the water column. As in other habitats, most acidic biofilms are composed of mixtures of different micro-organisms. The macroscopic shape and species composition of the biofilms vary greatly throughout these ecosystems. Some of them adopt filamentous morphologies in flowing water (Fig. 3(a–c)) while others form thick colourful patches firmly attached to the mineral substrates (Fig. 3(d–e)).

Some of the most extensively studied photosynthetic acidic biofilms are located in the Río Tinto (Spain). These biofilms are usually distributed on the riverbed as independent patches easily differentiated by their texture and color, although after microscopic observations some areas indicated mixing of communities mostly at the interface with the substrate. Most of the naturally grown biofilms are composed of different species organized in different layers separated by extracellular polymeric substances (Fig. 4).

Biodiversity studies show the presence of sequences related to uncultured organisms present in acidic or contaminated soil habitats, such as *Betaproteobacteria* and *Acidobacteria*, suggesting that biofilms appear to facilitate the development of less extreme adapted organisms coming from soil habitats. Besides, prokaryotic communities present in thinnest photosynthetic biofilms (<100 µm) resembled the biodiversity present in the water column, while thicker biofilms (>200 µm) show higher degree of prokaryotic diversity than in the water column. Thus, the presence of different environmental conditions inside the biofilms might explain why the greatest degree of prokaryotic diversity is associated with localities in which extensive photosynthetic biofilms are developed. The development sequence of the biofilms starts with the accumulation of unstructured material mainly formed by bacteria and inorganic particles of minerals. Within the next two months, fungi and some heterotrophs such as amoeba and flagellates (i.e., *Bodo* and cermonads) appear. After the mycelial matrix is formed, diatoms begin colonization, closely followed by green algae (*Dunaliella* and *Chlamydomonas*) as well as *Euglena*. Sessile species of algae such *Chlorella* or *Cyanidium* are the last colonizing microorganisms followed by the filamentous algae, *Zygnemopsis* and *Klebsormidium*.

Acidophilic micro-algae: Micro-algae are the dominant eukaryotic micro-organisms found in extreme acidic environments that are exposed to light. Chlorophyta such as *Chlamydomonas*, *Dunaliella* and *Chlorella* are frequently found (Fig. 5(a–b)). *Eunotia* and *Pinnularia* diatoms are also widely distributed in acidic environments (Fig. 5(c)). Filamentous algae from the genera *Klebsormidium* and *Zygnemopsis* are extremely abundant in summer months, producing large biomass areas on the water surface (Fig. 5(d)). The photosynthetic protist *Euglena mutabilis* is probably the most widespread species reported in acidic environments, being considered as a biomarker of low pH waters (Fig. 5(f)). The reasons for the dominance of these particular algal groups in these ecosystems are presumed to lie in their adaptive capabilities, their ecophysiological specialisation and the ecological advantages that they possess.

Apart from *Dunaliella acidophila*, the only other algal species reported to grow at pH 0 belongs to the order Cyanidiales. This order contains a group of asexual, unicellular red algae, which thrive in acidic (pH 0.5–3.0) and high temperature (50–55°C) conditions around hot springs and/or acidic sulfur fumaroles as well as in some acidic mining areas. Three genera (*Cyanidium*, *Cyanidioschyzon* and *Galdieria*) distributed in six species are identified in this order. Cyanidiales show a spherical morphology, one plastid, up to three mitochondria, a vacuole for products storage, the nucleus and are surrounded by a thick cell wall. The Cyanidiales is one of the most ancient groups of algae, located at the base of the Rhodophyta, and showing characteristics of Cyanobacteria. Within them, *Galdieria sulphuraria* is a remarkable species in terms of tolerance to high concentrations of metals and salt, exhibiting also a wide metabolic versatility, being able to grow photoautotrophically or heterotrophically using more than 50 carbon sources. *G. sulphuraria* is frequently found in volcanic hot sulfur springs, solfatar soils, and some contaminated anthropogenic environments. In habitats with high concentrations of toxic metals, easily represents up to 90% of total eukaryotic biomass.

Compared with prokaryotes, acidophilic micro-algae have received little attention, despite their abundance and remarkable presence in these environments. This might be due to them not being directly involved in geochemical transformations of iron and sulfur, though their indirect impact on these transformations can be considerable. For example, acidophilic micro-algae produce and secrete organic substrates (i.e., glycolic acid, fructose, glucose and mannitol) that stimulate the growth of acidophilic heterotrophic bacteria that can reduce both iron and sulfur/sulfate.

Acidophilic euglenoids and protozoa: *Euglena mutabilis* is one of the most abundant and conspicuous acidophilic micro-organisms in acidic environments. It has been described in acidic volcanic lakes, acidic geothermal areas and acidic mine waters, as is often considered a bio-indicator of the latter. *E. mutabilis* secretes metabolites, such as amino acids, polyamine compounds, urea and some sugars, into the external media that influences the composition and the metabolism of the whole microbial community.

Other groups of protozoa are frequently also found in acidic environments, and play key roles in the pelagic food web of acidic mining lakes. These include several species of ciliates (e.g., *Urotricha*, *Oxytricha* and *Frontonia* spp.), flagellates (e.g., *Ochromonas* and *Bodo* spp.), amoeba (e.g., *Vahlkampfia* and *Naegleria* spp.) and the heliozoan, *Actinophrys* sp. Many of these species are acid-tolerant rather than obligate acidophilic, and are able to grow over a broad pH range. In acidic pit lakes, the phytoplankton is often dominated by the mixotrophic flagellate *Ochromonas* spp. Ciliates seem to be of minor importance in these environments, relative to mesotrophic circum-neutral pH lakes.

Acidophilic fungi and yeasts: Acidophilic fungi and yeasts have received far less attention than algae or protozoa, although among the filamentous fungi isolated from acidic sites are some of the most acidophilic of all known micro-organisms: three species of filamentous fungi (*Acontium cylatium*, *Trichosporon cerebriae* and a *Cephalosporium* sp.) are able to grow at ca. pH 0. Most fungi found

Fig. 3 Microbial eukaryotic biofilms found in different acidic environments: (a) Green filaments formed mainly by *Klebsormidium* spp. in the Pachacoto River (Huaraz National Park, Peru); (b) filamentous *Zygnemopsis* spp. in the Rio Tinto (Huelva, Spain); (c) floating mats of filamentous zygnemas covered by iron oxides at Pastoruri Glacier (Huaraz National Park, Peru); (d) *Chlorella* spp. forming a thin layer over Rio Tinto sediments; (e) biofilms of the diatom *Pinnularia* spp. in the Seltun geothermal area (Reykjanes Peninsula, Iceland). The scale bar represents 10 μm .

in acidic habitats are, however, acid-tolerant rather than strictly acidophilic. Fungi play important roles in these environments because, together with other micro-organisms, they form biofilms on the surfaces of rocks. These biofilms are the site of metal and mineral precipitation and provide physical support for other microbial populations. Fungi can display metal resistance and can sequester specific metals allowing less tolerant species to exist. Recent studies have shown that biogenic formation of jarosite in

Fig. 4 SEM-BSE images of photosynthetic biofilms from Río Tinto: (a) Transverse section shows *Euglena* (Eug) and *Pinnularia* (Pin) species separated by an EPS layer (EPs), which dominate this biofilm above the rock fragments on the riverbed; (b) detailed image of same biofilm, showing a clear separation of the species; (c) transverse section showing *Pinnularia* (Pin) diatoms and *Chlorella* (Chlo), separated also by an EPS layer; (d) detailed image of the same biofilm showing bacterial communities (Bac) between *Pinnularia* (Pin) cells and some minerals (Min).

natural acidic environments, which is usually attributed solely to bacterial activity, is also enhanced by acidophilic fungi. *Purpureocillium lilacinum*, a fungal strain isolated from the Río Tinto, specifically precipitates hydronium-jarosite. The mineral starts to nucleate on the fungal wall of both living and dead cells as well as on extracellular polymeric substances (EPS).

Studies on yeasts in acidic environments are even scarcer and are usually related with *in situ* biodiversity, rather than adaptive mechanisms to acid stress. *Rhodotorula* spp., forming pink colonies, is usually found in acid mine drainage waters.

Adaptation Mechanisms in Eukaryotic Acidophiles

pH: As with prokaryotic acidophiles, the cytoplasmic pH of acidophilic eukaryotes is close to neutral, so they have to contend with extremely trans-membrane pH gradients. Acidophilic *Chlamydomonas* spp. have been reported to be able to survive a broad range of extracellular pH, by maintaining cytosolic pH values relatively neutral and faster rates of ATP consumption when living in acidic conditions than at neutral pH. Active proton extrusion into a cytosolic vacuole is suspected to be the pervasive mechanism that provides protection. Near neutral cytosolic pH may be maintained with the help of the contractile vacuoles in these micro-algae, without proton exchangers or transporters being exposed to the severe extracellular environment. In contrast, *Dunaliella acidophila*, one of the most extreme acidophiles known, shows a different adaptive mechanism for living at low pH. Several mechanisms have been described for its maintenance of trans-membrane pH gradients: (a) the existence of a potent plasma membrane H^+ -ATPase, (b) a positive surface charge and (c) a positive inside trans-membrane potential. In addition, the possession of positive surface charges is probably another factor that reduces the permeability of *D. acidophila* cells to protons, and also to cationic metals.

Heavy metals resistance: Since cation transition metals are often much more soluble in acidic liquors, acidophilic eukaryotes, like their prokaryotic neighbors, must be tolerant to elevated concentrations of metals to survive in many low pH environments. Their

Fig. 5 Light microscopy photographs of different eukaryotic species isolated from Río Tinto (Huelva, Spain): (a) Green algae *Dunaliella acidophila* cells; (b) Green algae *Chlorella* spp. cells; (c) *Pinnularia* sp. diatoms; (d) Filamentous of *Klebsormidium* spp; (e) Red algae *Galdieria* sp.; (f) Photosynthetic protist *Euglena mutabilis*; (g) Heliozoa *Actinophrys* sp. Scale bar=10 μ m.

ability to survive high metal concentrations in acidic environments is due to a combination of extracellular passive and intracellular active systems. Within the passive resistance mechanisms, eukaryotic acidophiles usually form biofilms including extracellular polymeric substances (EPS) that can sorb metals to provide a further degree of metal tolerance. (Fig. 6).

The most frequent defence mechanism against heavy metal stress found in eukaryotic cells is the production of peptides capable of binding heavy metals, such as phytochelatines and metallothioneins. These molecules, as organometallic complexes, are further partitioned inside vacuoles to facilitate appropriate control of the cytoplasmic concentration of heavy metal ions, thus preventing or neutralizing their potential toxic effect. A recent study regarding transcriptomic response to cadmium, identified novel phytochelatin synthase (PCS) genes from two acidophilic green algae, *Dunaliella acidophila* and *Chlamydomonas acidophila* strains isolated from the Río Tinto. These novel PCS genes appeared to have a bacterial origin and were subsequently inherited by different groups, in some cases multiple times.

Acidophilic organisms are also able to transform metal species to less toxic or bioavailable forms. For example, *Cyanidium caldarium* is able to oxidize, reduce, and methylate arsenical compounds, the latter process leading to the generation of volatile arsenic species such as trimethylarsine oxide. In addition, *E. mutabilis* has been shown to be particularly tolerant to arsenic, which could depend on a novel response to the presence of this toxic metalloid. Transcriptomic analysis performed on both *Euglena* species, revealed that *E. mutabilis* avoids the accumulation of arsenic in the cell through the expression of several transporters, and can induce the expression of active DNA repair and protein turnover mechanisms, which allow *E. mutabilis* to maintain functional integrity of the cell under challenging conditions. Taken together, all these results suggest the existence of a specific arsenical response of *E. mutabilis* that may play a role in its hyper-tolerance to this toxic metalloid. Transcriptomic data and metabolomics approaches carried out in *Coccomyxa* sp., a micro-algae isolated from the AMD of Carnoulès (France), highlighted also the induction

Fig. 6 Electron micrographs of acidophilic eukaryotic micro-organisms and biofilms from the Río Tinto (Huelva, Spain): (a) SEM of *Dunaliella acidophila*; (b) SEM micrograph of *Chlorella acidophila*; (c) LTSEM image of a natural *Chlorella*-dominated biofilm, arrows point to the mineralized EPS around the cells; (d) transmission electron micrograph of an amoeba isolated from the river, with electron-dense vacuoles containing transition metals arrowed; (e) SEM of *Chlamydomonas acidophila* cells surrounded by EPS; (f) SEM of *Chlorella* spp. encased by EPS. The scale bar represents 10 μm , unless indicated otherwise.

of a set of transporters that could potentially prevent internal accumulation of arsenic. Electron microscope observations have indicated the presence of electron-dense bodies in vacuoles in *Chlamydomonas acidophila* and *Cyanidium caldarium*, as well as in other micro-algae species, treated with heavy metals. These dense bodies contain heavy metals, suggesting that metal deposition in vacuoles is also a mechanism that may contribute to heavy metal tolerance. Metal accumulation in vacuoles seems to be the most effective system for maintaining low cytoplasmic metal concentrations.

Nutrient limitations: Most extremely acidic environments contain relatively low concentrations of inorganic carbon (Ci) and phosphorus (Pi), and may therefore be considered oligotrophic, limiting the growth of autotrophic organisms. The low pH of acidic waters dictates that negligible concentrations of bicarbonate are present, and dissolved CO_2 is the sole inorganic carbon source. *Chlamydomonas acidophila* can accumulate Ci and shows high affinity CO_2 utilization under low- CO_2 conditions, similar to organisms with an active CO_2 uptake mechanism, although both processes are down-regulated under high CO_2 conditions. Thus, Ci availability is improved in *C. acidophila* under ecologically relevant conditions, which may enable optimal survival in its extreme Ci- and Pi-limited habitat. A further metabolic advantage is the ability of acidophilic micro-algae to produce phosphatases. This is an apparent adaption to the poor nutrient situation in these pit lakes and other acidic mine waters, and may be induced by aluminum. *C. acidophila* responds to phosphate deficiency not only by enhancing total phosphatase activities but also by producing another phosphatase with an optimum at pH 2. This is thought to be one reason why *C. acidophila* is one of the most abundant eukaryotic species in both extreme acidic environments, mining-impacted areas and volcanic habitats.

Photosynthesis: It is well known that photosynthesis is highly sensitive to stressful environmental conditions, such as pH and temperature extremes, and the presence of toxins. However, it appears that metal stress or low phosphate concentrations rather than elevated hydronium ion concentrations limit photosynthetic activity in extremely acidic environments. Light is often a limiting factor for primary productivity in acidic lakes, due to the presence of particulate materials and soluble ferric iron. Adaptation to low light intensities has been reported for benthic biofilms of diatoms in acidic lakes, where photosynthesis at low light intensities has been described, suggesting an efficient absorption of red light, the dominant wavelength available in these iron-rich acidic waters. All of the photosynthetic biofilms analyzed at Río Tinto (euglenas, chlorellas and diatoms biofilms) are acclimatized to low light intensities, and are mostly located at the bottom of the river bed, covered by several centimeters of a highly colored red water, while in contrast filamentous *Zygnemopsis* spp. float on the water surface, where the sun irradiance is extremely high during the summer. This difference in their ecological niches may explain their different photosynthetic behavior. Intense solar radiation can induce large-scale transcriptomic reprogramming during midday periods, though this is due to UV radiation rather than to light intensity. In order to minimize the negative effects of solar radiation, the transcriptomic results support the presence of a circadian rhythm in this euglenophyte that increases their opportunity to survive, with photosynthetic related processes enhanced in the morning, DNA synthesis occurring in the evening, and cell division taking place at night. The transcription pattern during the day is mainly altered in genes involved in Photosystem II stability and repair, UV damaged DNA repair, non-photochemical quenching and oxidative stress. Adaptation to low light intensities has also been reported in *Galdieria* and *Cyanidium*, which often grow endolithically (within rocks), and therefore, autotrophic cell growth is restricted to upper rock layers and/or to periods of high photosynthetically-active irradiation.

Biotechnological Applications of Acidophilic Eukaryotes

Cultivation and exploitation of extremophile micro-organisms has attracted interest due to their ability to accumulate high-value compounds, including various metabolites, enzymes and surfactants. Recent genetic studies on acidophilic algae may lead to novel biotechnological applications. During the last decade, several biotechnological approaches using acidophilic micro-algae have been reported with the food industry (carotenoids production, lipid bioaccumulation) and bioremediation of metal-contaminated environments as the main areas of interest.

Acidophilic micro-algae as a food supply: The use of micro-algae as a food source for humans and animals has been increasing since the early 1950s. Micro-algae can represent a valuable source of both vitamins and fatty acids and, because of the high protein content of some species, they could also have potential for manufacturing food-stocks both for humans and animals. Although micro-algae are usually photosynthetic organisms, a few species are able to grow under heterotrophic conditions. This possibility opens a promising field of research, through the use of cheap fermenters instead of expensive photo-bioreactors, allowing high densities of micro-algal cells and therefore high yields. In this respect, *Galdieria* species are of particular interest as they grow between pH 1.5 and 2.0, thus preventing contamination with pathogenic bacteria, which is one of the key problems of large scale micro-algae cultures. Heterotrophic cultures of *Galdieria sulphuraria* contain high levels of phycocyanin, a pigment used as a dye in food and cosmetics as well as a fluorescent marker in medical diagnostics. In addition, *Galdieria* species also have significant potential as a source of protein and other macronutrients due to the high protein contents of their cell walls. The difficulties in introducing micro-algal-based ingredients in many foods are due to the strong green color and the susceptibilities of lipid moieties to oxidation, but the peculiar features of *G. sulphuraria* have the potential to overcome these obstacles. Nutritional analysis of 43 strains of *Galdieria* showed that they were rich in proteins (26%–32%) and polysaccharides (63%–69%) but contained relatively small amounts of lipids. Under heterotrophic cultivation conditions, the lipid moiety mainly contained monounsaturated fatty acids, suggesting that *G. sulphuraria* biomass has a potential use as food ingredients both for protein-rich or insoluble dietary fibre-rich applications.

Some issues related with the use of micro-algal biomass as a direct food source for animals have been reported, including their high nucleic acid content and possible contamination, and concern has been raised regarding potential toxicity and long-term effects on human health. Due to this, the future use of micro-algae biomass in the food industry is likely to be primarily as a source of nutraceuticals for functional foods rather than the direct use of such biomass. However, studies carried out with the acidophilic micro-algae *Coccomyxa onubensis* as dietary supplementation in laboratory rats have shown no adverse effects on rat health. In addition, *C. onubensis*-supplemented diets exhibited a potent hypocholesterolemic and hypotriglyceridemic effect in experimental animals. These results support the idea that acidophilic species might be better model systems for investigating the potential use of microalgae in animal feed.

Acidophilic micro-algae as source of industrially interesting compounds; anti-oxidant carotenoids and lipids: The extreme oxidative conditions of acidic environments suggest that acidophilic micro-organisms should express anti-oxidant mechanisms to defend themselves from oxidative stress. For this reason, the biotechnological value of several species of acidophilic micro-algae has been analyzed. *Chlamydomonas acidophila* accumulates high concentrations of lutein, a well-known antioxidant also known to be accumulated by other micro-algae; this compound has recently attracted interest for use in treatment of oxidative pathologies such as macular degeneration. Mixotrophic growth of *C. acidophila*, in terms of carotenoid production, resulted in even higher productivity of carotenoids (mainly lutein) than obtained with photo-autotrophic cultures. The accumulated lutein concentrations of *C. acidophila* under these conditions (about 10 g/kg dry weight) are among the highest reported for a microalga. Similar results were obtained with *Coccomyxa onubensis* (about 6 g lutein/kg dry weight).

The use of micro-algae as a carbon neutral source of biofuel has also been considered in recent years. Current micro-algae biofuel methodologies usually depend on growing high-lipid producing laboratory strains of micro-algae in open or closed photo-bioreactors. Unfortunately, these micro-algae species are usually highly sensitive to competition by indigenous strains or to environmental stresses. Contamination by invasive species can decrease productivity of commercial processes, increasing the price of production. The use of high-lipid acidophilic algae which thrive in restrictive culture conditions that reduce the risk of contamination could help to solve the contamination problems. Cultures of acidophilic micro-algae *Scenedesmus* spp. and a *Pseudochlorella* sp., have shown to accumulate high amount of storage lipids (30% of dry weight) by cultivating them in sulfuric acid-containing open ponds (generated from mine drainage waters), acidic hot springs or industrial wastes, demonstrating their potential use in next-generation biofuel industry.

Although current knowledge of oil accumulation mechanisms in micro-algae is relatively sparse, recent studies have yielded information on how to increase the cellular oil by genetic manipulation in tractable model algae such as *Chlamydomonas reinhardtii*, and also procedures for transformation in several other algal species. These developments and a further screening of algal strains from acidic environments could enhance oil productivity and biomass in acidic open ponds in the future.

Acidophilic eukaryotes and bioremediation: Typically, high water consumption in mining operations results in large amounts of waste water contaminated with heavy metals, salts and various other inorganic compounds. Traditional water treatment techniques such as reverse osmosis and membrane filtration are energy intensive and costly, and the use of micro-organisms to remove heavy metals and other potentially harmful inorganic materials in waste waters is a promising alternative. Extracellular polymeric substances (EPS) have attracted attention because of their biotechnological potential in removing contaminants, especially heavy metals. Acidophilic micro-organisms could play an important role in this area, since their EPS production is several orders of magnitude higher than in neutrophilic species. The potential for heavy metal remediation growing endemic acidophilic micro-algae biofilms was illustrated with phosphorus-enriched water from a nickel refinery. Indigenous *Chlorella*-like micro-algae and biofilms were shown to remove up to 25% from the total metals present. In addition, the use of *Galdieria sulphuraria* for the recovery of metals, and particularly rare earth metals, has also been explored. *G. sulphuraria* was able to recover lanthanoids ions present at only 0.5 mg/L with greater than 90% and, at pH between 1.0 and 1.5, the lanthanoids were sequestered much more efficiently into cell biomass.

Bioprospecting for new species and strains could well identify new may identify novel acidophilic micro-algae that have even more useful characteristics for emerging biotechnologies. Acidophilic eukaryotes are currently an under-exploited resource that requires to be further investigated.

Ecosystems and Interactions

Extremely acidic environments can develop in a range of ecological niches. Within them, microbial communities of varying complexities occur within which individuals interact with each other in a wide variety of ways. These interactions, in turn, can have major impact of the geochemical dynamics of these extreme environments.

Diversity of Extremely Acidic Environments

(1) **Geothermal Areas.** Geothermal areas occur in discreet zones in various parts of the world. The most well-studied land-based geothermal area is Yellowstone National Park, Wyoming, U.S.A., where the acidity is derived chiefly from the oxidation of sulfur. Much of the early pioneering microbiological work in Yellowstone was carried out by Thomas Brock and co-workers in the 1970s and formed the basis of later research on thermophilic micro-organisms (including thermo-acidophiles). One of the major breakthroughs around the time was the isolation, by James Brierley, of the first thermophilic acidophile (a *Sulfolobus*-like archaeon, though it was not recognized as such at the time) from an acid hot spring in Yellowstone. Two of the more important solfatar fields in Yellowstone are located in and around the Norris Geyser Basin, and at Sylvan Springs, though there are numerous other smaller scale, often ephemeral sites (such as around the Gibbon River) where acidic ponds and streams may be found. Moderately thermophilic and acidophilic phototrophs (*Galdieria*/*Cyanidium*-like rhodophytes), Gram-positive (*Sulfobacillus*, *Alicyclobacillus*, *Acidibacillus*, *Acidimicrobium* and *Ferrithrix* spp.) and Gram-negative (*Acidicaldus* and *Hydrogenobaculum* spp.) bacteria have been isolated from these and other sites. Mesophilic bacteria, such as *Acidiphilium* spp., are more abundant in cooler, extremely acidic sites. In contrast, sulfur-oxidizing crenarchaeotes (species including *Sulfolobus*, *Sulfosphaera*, *Metallosphaera* and *Stygiolobus*) dominate hotter low pH environments in Yellowstone.

Other geothermal areas where the distribution of acidophilic micro-organisms has been studied include New Zealand, the Caribbean island of Montserrat, and northern California. A site in New Zealand, an acidic (pH 2.5) stream water on White Island, contained significant concentrations (2–4.4 g/L) of chloride in addition to soluble iron and sulfate. Among the clones identified from DNA extracted directly from the acid stream were those closely related to a green sulfur bacterium (*Chlorobium vibrioforme*), the marine, purple non-sulfur bacterium *Rhodovulum*, and the heterotrophic bacterium *Ralstonia solanacearum*, while those obtained from enrichment cultures also included a bacterium that was closely related to *Acidicaldus organivorans*. Pure cultures of *Acidiphilium* and *Cyanidium caldarium* were also obtained from the site. Results of a large-scale survey of

- geothermal sites (many of which were also extremely acidic) on Montserrat, carried out shortly prior to the major eruption of the Soufriere Hills volcano in 1996, showed that temperatures of pools and streams in the volcanic southern region of the island ranged from 30 to 99°C, and pH from 1.0 to 7.4. Most of the acidophilic bacteria that were isolated were similar to known strains, though some *Sulfobacillus*-like isolates had novel traits in being able to grow either as mesophiles, or at higher maximum growth temperatures (up to 65°C) than classified species. Clone libraries constructed from DNA extracted from acidic sites with different temperatures indicated the presence of: (i) *Acidiphilium*-like bacteria and *Acidithiobacillus caldus* (33°C site); (ii) *At. caldus*, and a putative moderately thermophilic sulfate-reducing bacterium of the *Desulfurella* group (48°C site); (iii) novel *Ferroplasma*-like and *Sulfolobus*-like archaea (78°C site); (iv) an archaeon distantly related to *Acidianus infernus* (98°C site). Elsewhere, a microbiological survey of high temperature (82°–93.5°C) acidic (pH 1.2–2.2) hot springs located in the Lassen Volcanic National Park in northern California failed to detect any bacteria, though archaea distantly related to the crenarchaeotes *Stygiolobus azoricus* and *Sulfolobus solfataricus* (both extreme thermo-acidophiles thermophiles) were identified in clone libraries. Extremely acidic pools and lakes may develop naturally in volcanic areas, for example, Lake Kawah Idjen in Indonesia, which has a pH of ~0.7. The Copahue volcano is the source of geothermal activity in the Neuquén province of Argentina, where acidic ponds, pools and hot springs input into the acidic Rio Agrio, which in turn discharges into a large low pH water body, Lake Caviahue. Microbial diversity and interactions in the acidic environments in this region are dictated primarily by pH and temperature, and a wide range of known species, as well as novel species (e.g., the thermo-acidophilic archaeon *Acidianus copahuensis*) have been isolated from and identified within Copahue-Caviahue.
- (2) Acid mine drainage waters and pit lakes. Waters draining abandoned mines, mine spoils and mineral tailings deposits (often referred to as acid mine/rock drainage) are often characterized by low pH and elevated concentrations of soluble metals (particularly iron) and sulfate (Table 2). Mineral acidity, due to the presence of dissolved aluminum, manganese and iron can contribute greatly to the net acidity of these water bodies. Pit lakes are relics of open-cast coal and metal mining, where worked out voids have not been back-filled and become progressively filled with rising ground water or river water. Where the surrounding bedrocks are rich in sulfide minerals (normally chiefly pyrite and marcasite) and contain small amounts of carbonates, the oxidative dissolution of the former can lead to the formation of extremely acidic mine lakes. Acidic pit lakes are particularly abundant in central Europe (Germany, Poland and the Czech Republic) where extensive reserves of lignite have been extracted (and still are on a more limited scale) by open-cast mining on a massive scale, leaving a legacy of a very large number of man-made lakes of varying sizes and chemistries. In the Lusatia district of eastern Germany alone there are an estimated 200 mining lakes of > 1 ha that have pH values of <3. Pit lakes resulting from opencast metal mining have more complex chemistries and can develop more extreme acidity, particularly in their upper (oxidized) zones. The often complex microbial geochemistries of these water bodies are described in a later section of this article.

Knowledge of the biodiversity of mine drainage has expanded considerably since *Acidithiobacillus ferrooxidans* was first isolated from a stream draining a bituminous coal mine in the U.S.A. in 1947. The most important factors in determining which microbial species are present in mine waters appear to be pH, temperature and concentrations of dissolved metals and other solutes. The Richmond mine at Iron Mountain, California, which can have negative pH values, represents the most extreme end of this spectrum, and the microbiology of water bodies within the mine has been studied extensively. At this site, pyrite is undergoing oxidative dissolution at a rate that is sufficient to maintain air temperatures of between 30 and 46°C, and produce mine waters containing ~200 g/L of dissolved metals. A novel iron-oxidizing archaeon, *Ferroplasma acidarmanus*, was found to be dominant in waters within the mine that had the lowest pH and highest ionic strengths, while *Leptospirillum ferriphilum* and *L. ferrodiazotrophum* were also associated with exposed pyrite. *Sulfobacillus* spp. were more important in some of the warmer (~43°C) waters. Iron-oxidizing acidithiobacilli were rarely found in sites that were in contact with the ore body, though they were found in greater abundance in the cooler, higher pH waters that were peripheral to the ore body. In contrast, a

Data are from Johnson, D.B., 2006. Biohydrometallurgy and the environment: Intimate and important interplay. *Hydrometallurgy* 83,153–166. And Nordstrom, D.K., Alpers, C.N., Ptacek, C.J., Blowes, D.W., 2000. Negative pH and extremely acidic minewaters from Iron Mountain, California. *Environmental Science and Technology* 34, 254–258.

microbiological survey of much cooler and higher pH mine waters at an abandoned sub-arctic copper mine in Norway found that the psychro-tolerant acidophile *Acidithiobacillus ferrivorans* was the dominant iron-oxidizer isolated. This *Acidithiobacillus* sp. has been found in many cold, acidic and iron-rich surface and sub-surface environments, ranging from Siberia to Antarctica, where its ability to remain metabolically active where other species are inactive clearly presents it with a strategic advantage. Heterotrophic extreme acidophiles (*Acidiphilium* and *Acidocella* spp.) have also been encountered in permanently and transiently low temperature acidic environments. *Ferrovum myxofaciens* (which is also psychro-tolerant) is also frequently encountered in such environments, particularly in flowing waters > pH 2.

- (3) *Acid streamers, mats and slimes in surface and sub-surface low pH environments*: The most obvious and dramatic manifestations of microbial life in extremely acidic environments are macroscopic growths, referred to as acid streamers, slimes and mats (Fig. 7). Streamers may occur in flowing AMD streams within and outside of abandoned mines; these have distinct filamentous morphologies and each filament may be more than a meter in length. Acid mats are more dense in texture, and are often found below growths of acid streamers. Acid slimes are thick, macroscopic biofilms that grow on moist surfaces of exposed rock faces. In addition, macroscopic filaments (or pipes) composed of acidophilic micro-organisms may attach to, and suspend from, mine roofs and pit props. Where these are small-scale, they have been referred to as snotites, though larger structures have been described as microbial stalactites (Fig. 7(a)). Because of the macroscopic nature of acid streamer growths, they were among the first life-forms to be reported in extremely acidic environments (in 1938). Most of the early reports described acid streamers as being composed of bacteria embedded in a gelatinous matrix. The first attempts, in the 1970s, to characterize their component micro-organisms used classical microbiological (cultivation-based) techniques. In the main, neutrophilic (chiefly spore-forming *Bacillus* spp.) were isolated from the acid streamers examined, leading to the erroneous conclusion that acid streamers were composed of neutrophilic heterotrophic bacteria that maintained circum-neutral pH within the macroscopic growths. In contrast, other researchers noted that streamers found in an iron/sulfur mine in Japan were able to catalyze the oxidation of both ferrous iron and sulfur, though some sub-samples of streamers have very limited capacity to oxidize iron. *Acidithiobacillus ferrooxidans*-like bacteria were isolated from these growths, leading researchers to conclude that acid streamers were a mass of iron-oxidizing acidithiobacilli embedded in a gelatinous matrix. However, it is only since biomolecular tools

Fig. 7 (a) Microbial slime and stalactite growth deep underground in an abandoned copper mine (Mynydd Parys, Wales); (b) growths of micro-algae on bacterial acid streamers in the Rio Tintillo, Spain; (c) stratified acid streamer/mat growths in a drainage channel at the abandoned Cantareras copper mine, Spain.

have been used to analyze acid streamers and related macroscopic growths that their true nature has been elucidated. This approach, coupled with major advances in techniques for isolating and cultivating acidophiles made over the past 30 years, has shown that streamer communities are both highly complex and vary from site to site. Superficial similarities in their gross morphologies may mask completely contrasting microbial diversities.

One of the first intensive biomolecular examinations of acid slime (~1 cm thick) and snotite growths was carried out with materials collected from the Richmond mine at Iron Mountain. Microscopic examination showed that both growth forms were composed mostly of spirillum-shaped cells embedded in an extracellular polymeric matrix. Phylogenetic analysis based on 16S rRNA genes showed that most of the recovered sequences were novel, but related to known iron-oxidizing acidophiles. The single most dominant sequence recovered from the slime growths were of a novel strain of *Leptospirillum* (subsequently named *L. ferrodiazotrophum*). *L. ferrophilum*-related clone sequences were also identified. Other iron-oxidizing Bacteria identified were related to the Gram-positive actinobacteria, *Acidimicrobium* and *Ferrimicrobium*, while sequences that affiliated with deltaproteobacteria (which includes anaerobic sulfate- and iron-reducers) were also detected, suggesting that micro-zones of low redox potential existed within the macroscopic growths. Archaeal genes were also amplified, and sequences related to *Ferroplasma acidarmanus* identified. Other archaeal sequences were, however, only distantly related to known Archaea. In contrast to the Richmond mine slimes, acid streamer growths in less extremely acidic and cooler sites in north Wales were both found to be composed predominantly of Betaproteobacteria, occasionally with large numbers of Acidithiobacillaciae. *Ferroplasma myxofaciens* was identified as the dominant betaproteobacterium, and *Acidithiobacillus ferrivorans* as the other dominant Proteobacterium, which correlated with their known traits of psychro-tolerance and tolerance to acidity above pH ~2.

Other subterranean extremely acidic sites that have been subjected to detailed investigation include abandoned pyrite mines in Wales and Germany, a copper mine (again in Wales) and a sulfur-rich cave system in Italy. The abandoned Cae Coch pyrite mine in north-west Wales is home to the most extensive and diverse macroscopic acidophile growths yet reported, with an estimated acid streamer biovolume of >100 m³ alone, in addition to extensive slime biofilms and mats, microbial stalactites and snotites. Although the temperature in the mine shows very little seasonal fluctuation (8.5+/-1°C), other physico-chemical factors, including pH, dissolved oxygen and concentrations of dissolved metals and other solutes, vary from site to site within the mine. This, together with the fact that the underground mine has been largely undisturbed for 90 years, has facilitated the colonization of different niches by different streamer/slime acidophilic communities. *Ferroplasma myxofaciens* and *Acidithiobacillus ferrivorans* are again highly abundant in this underground mine, together with smaller numbers of other extreme acidophiles (e.g., *Leptospirillum*, *Ferrimicrobium*, *Acidiphilium* and *Acidocella*) and moderate acidophiles. The abandoned Drei Kronen und Ehrte pyrite mine in the Harz Mountain area of central Germany also contains small microbial stalactite-like structures attached to the mine ceiling. Molecular analysis of the microbial growths showed that they were dominated by *Leptospirillum*- and *Ferroplasma*-like bacteria with smaller numbers of heterotrophic (*Acidiphilium*-like) bacteria. Archaeal sequences closely related to those detected in Iron Mountain, and also to uncultivated members of the Thermoplasmatales have been detected in the biofilm communities in this site.

Mynydd Parys in north Wales was, in the 18th century, the world's most productive copper mine, worked initially as a deep mine and later as an opencast operation. The underground workings were drained in the early 21st century, allowing previously inaccessible areas to be explored. Large, two-dimensional gelatinous materials, referred to by the early cavers as "drapes" hanging from previously inundated pit props were discovered, together with microbial stalactites and streamer-like materials were found to be growing from the adit roofs and in newly-formed pools. Bacteria in the "drapes" were related to heterotrophic, rather than autotrophic, acidophiles, and included two species (*Ferrimicrobium* and *Acidimicrobium*) that are known to both oxidize and reduce iron and another (*Acidobacterium* spp.; moderate acidophiles) known to catalyze the dissimilatory reduction of iron (III). Archaea were also detected by molecular methods, most of which were related to methanogenic euryarchaeotes.

The Grotta Grande del Vento-Grotta del Flume (Frasissi) cave complex, Italy, is an example of a sulfidic cave formed when sulfide-rich groundwaters contact oxygen within subterranean carbonate rock strata. Sulfuric acid formed by (microbiological) oxidation of the sulfide results in the dissolution of the carbonate minerals, a process that can lead to the development of extensive cave systems, also found elsewhere.

In the Frasissi cave, viscous biofilms occur in extremely low pH (0–1) waters. The pendulous biofilms ("snotites") have very limited biodiversity, and are dominated by bacteria related to the mesophilic sulfur-oxidizing autotroph *Acidithiobacillus thiooxidans*. Other bacteria identified include bacteria related to Gram-positive *Sulfobacillus* and *Acidimicrobium* spp., and archaea related to *Ferroplasma*. Interestingly, although *Sulfobacillus* spp., like *Acidithiobacillus* spp., can use reduced sulfur species as electron donors, those *Acidimicrobium* and *Ferroplasma* spp. that have been characterized are known to oxidize ferrous iron but not sulfur, raising the probability that the latter two species in Frasissi (where ferrous iron is not a significant source of energy) represent new phenotypes. Other microorganisms detected within the slime growths include protists and filamentous fungi, as well as uncharacterized bacteria.

Streamer-like growths are also commonly found in flowing extremely acidic waters outside of mines, but here access to solar energy promotes the growth of micro-algae as well of chemolitho-autotrophic prokaryotes, and streamer growth often have surface green colorations (Fig. 7(b)). The addition of phototrophic biomass adds to the biodiversity of these ecosystems both directly and indirectly. One such site that has been studied in detail is a small abandoned copper mine (Cantareras) in south-west Spain. Surface growths grow as a dense microbial mat; that fills the ~100 m long drain channel and show distinct stratification (Fig. 7(c)). The surface layer is green due to the presence *Zygnema*, *Chlamydomonas* and other phototrophic eukaryotes that both aerate the anoxic mine water and provide organic carbon which supports the growth of bacteria within the mat. In contrast to most other acid streamer communities that have been described, heterotrophic (mostly iron-reducing) acidophiles dominate sub-surface layers at

Cantereras. Complex biogeochemical cycling of iron (acting as both electron donor and electron acceptor) and sulfur in the Cantereras streamer community helps to sustain the highly diverse population of acidophiles that occurs there.

Microbial Interactions at Extremely Low pH

Extremely acidophilic bacteria, archaea and eukaryotic microorganisms live, sometimes in very close proximity, with others of their own species and with different species, and within these communities they can exhibit a variety of interactions which may have positive, negative or nil effects on their neighbors. Most of the types of interactions that occur between microorganisms in environments considered to be non-extreme have also been observed in those that are extremely acidic. These include: (i) *Neutral symbioses*, in which neither partner derives any positive or negative effect from sharing an environmental niche (these tend to be relatively rare); (ii) *positive symbioses*, where one or more partners derive some benefit from sharing an environmental niche. These include: (a) mutualistic interactions, where both partners derive benefit from their association; (b) commensalism (or facilitation), where only one of the partners is perceived to derive benefit; (c) synergistic interactions that result in the complimentary activities of both (or all) participants being more efficient in, for example, degrading a substrate, than the individual species working alone; (d) syntrophy, where the degradation of a substrate by one species is only made thermodynamically possible through the removal of an end product by another species; (iii) *negative symbioses* (also referred to as antagonism), in which the activities of one or both partners sharing an environmental niche are impaired or suffer more serious negative impact. These include: (a) competition, where populations of co-habiting species are limited by their communal requirement of an electron donor, electron acceptor or inorganic nutrient (nitrogen, phosphorus, carbon dioxide etc.) which is present in limited quantities; (b) amensalism, in which one species can repress another, e.g., via the production of toxin(s); (c) predation, where one organism is ingested by another.

One of the first mutualistic interactions amongst acidophilic bacteria to be recognized was the flow of organic carbon from chemo-autotrophic acidithiobacilli to obligately heterotrophic *Acidiphilium* spp.. The latter have longed been known to grow, sometimes cryptically, in “inorganic” liquid media used to cultivate iron- and sulfur-oxidizing chemolitho-autotrophs. Some of the carbon dioxide fixed by the latter and incorporated into organic molecules is leaked into the surrounding media during their growth, and also arises from lysed cells. Some of these organic materials are oxidized back to CO₂ by the heterotrophs, and this in turn benefits the autotrophs in two ways. Firstly, certain organic exudates and lysates are toxic to the carbon-fixers, and can inhibit their growth, especially in closed systems, and their removal is therefore advantageous. Secondly, it has been demonstrated that some of the CO₂ generated is actually re-incorporated into biomass by the acidithiobacilli. This is potentially an important source of inorganic carbon for these bacteria, as the availability of CO₂ is often limited (due to its poor solubility in acidic liquors) in low pH environments.

Symbioses involving microbial redox transformations of iron and sulfur are also important in low pH environments. Ferrous iron acts as an electron donor for many acidophilic prokaryotes, which oxidize it to ferric iron, which in turn has widespread use as an electron acceptor in oxygen-limited (or depleted) environments. Since both ionic forms of iron are soluble at pH <2.5, they can freely diffuse between, for example, aerobic surface waters and underlying micro-aerobic or anoxic sediments. Dynamic oxidation of iron is a feature of many extremely acidic environments. This is true also, to some extent, for sulfur. Many acidophilic prokaryotes, as noted previously, can oxidize reduced forms of sulfur, ultimately to sulfate. Sulfate-reducing bacteria (which catalyze the dissimilatory reduction of sulfate to hydrogen sulfide) are widely distributed in anoxic sediments etc., including those in low pH stream and lake sediments. Several species of acid-tolerant, though not extremely acidophilic, sulfate reducing bacteria have been isolated from these environments and shown to be involved in sulfur cycling *in situ*.

The importance of microbial consortia and interactions in commercial bio-processing of sulfide minerals is well established. Three “groups” of acidophiles are ubiquitous in these operations. The first, and most important, are iron-oxidizing (mostly autotrophic) acidophiles which generate ferric iron, the oxidant that solubilizes the minerals. Iron-oxidation is, as noted, a proton-consuming reaction, which is ultimately counter-productive to the process, which requires low pH to maintain ferric iron in solution. The second players in the consortia oxidize reduced sulfur released from the partly-oxidized minerals to sulfuric acid, thereby maintaining suitable pH for both the process and the prokaryotes involved. Again these are mostly autotrophs, and organic carbon from these (and the iron oxidizers) is degraded by the “janitor” members of the consortium (heterotrophic acidophiles), which both de-toxify the liquors and release CO₂ for the autotrophs. A schematic of this system is shown in Fig. 8.

A more rarified consortium, comprising just two acidophiles that can successfully thrive by degrading pyrite together which neither has the potential to do this alone, has also been described. *Ferrimicrobium acidiphilum* is an obligately heterotrophic acidophile that oxidizes ferrous iron and can degrade sulfide minerals such as pyrite when provided with a source of organic carbon, such as yeast extract. *Acidithiobacillus thiooxidans* is an autotrophic acidophile that oxidizes reduced sulfur, but not iron, and can therefore not oxidize pyrite. Pure cultures of either organism (in inorganic media) show no potential to grow on and degrade pyrite, but mixed cultures of the two can thrive on this mineral. Interactions involve inter-related flows and transformations of iron, sulfur and carbon, as depicted in Fig. 9.

Although biogeochemical cycles in extremely acidic environments usually center on transformations of iron, sulfur and carbon, they can involve other elements which in turn can have overriding influences on the nature and dynamics of these environments. This is clearly seen in the case of acidic pit lakes that form in abandoned metal mines. Studies carried out in several sites in Spain have revealed an intriguing level of geomicrobiological complexity within them. These pit lakes can be deep (>50 m) and have characteristic permanent stratification, with the water column composed of an upper oxic layer which displays seasonal variation in temperature, a bottom anaerobic layer which has a more limited temperature range, and a transitional zone (the chemocline)

Fig. 8 Microbial consortia and interactions involved in the oxidative dissolution of sulfidic minerals, such as pyrite (FeS_2 ; illustrated) at low pH. Iron-oxidizers are primarily responsible for degrading the minerals, while sulfuric acid-generating and organic carbon-degrading acidophiles maintain conditions that are conducive for the process to continue.

Fig. 9 Dissolution of pyrite by a mixed culture of *Ferrimicrobium acidiphilum* and *Acidithiobacillus thiooxidans*. *Fm. acidiphilum* can oxidize ferrous iron to ferric iron but requires organic carbon to grow. *At. thiooxidans* can fix CO_2 and releases some of this as organic carbon, but it cannot access its energy source (reduced sulfur) directly from pyrite. Neither bacterium can therefore grow in organic carbon-free pure cultures using pyrite as an energy source, though together they form a successful synergistic consortium.

Fig. 10 Geochemical stratification of a typical pit lake formed by the flooding of an abandoned opencast metal mine in the Iberian Pyrite Belt. The green-shaded area indicates the zone where algal numbers and activity (and primary production) are greatest.

separating them. Dynamic cycling of iron and sulfur, and fixation and catabolism of organic carbon, occur in these lakes. An apparent major anomaly identified in pit lakes in the Iberian Pyrite Belt was that maximum primary production and accumulation of algal biomass occurred at depths where photosynthetically-active radiation was <2% of that close to the water surface. While concentrations of inorganic nitrogen were found to be fairly uniform throughout the water columns in these lakes, phosphate was present in far greater concentrations in the anoxic bottom waters than in the aerobic surface waters. Further investigations showed that this was due to the formation of insoluble ferric phosphate in the upper waters, corresponding to the microbial oxidation of ferrous iron in and above the chemocline, leading to the formation of insoluble ferric phosphates. Algal growth and activity was therefore dictated primarily by the availability of phosphate in these iron-rich lake waters, rather than by the intensity of sunlight. The chemoclines (which were about 2 m in depth in these pit lakes) were demonstrated to be the zones within the water columns that housed the greatest biodiversity and numbers of micro-organisms, and where the geochemical cycling of carbon, iron and sulfur were most dynamic (Fig. 10).

Glossary

Barophilic Descriptor for cultured members of the domain Bacteria or Archaea that grow more rapidly under elevated hydrostatic pressures of the deep sea than at atmospheric pressure (also piezophilic).

Barotolerant Descriptor for cultured members of the domain Bacteria or Archaea that grow under elevated hydrostatic pressures but more rapidly at atmospheric pressure.

Cold-active General descriptor for enzymes that are catalytic or viruses that are infective at low temperature.

Cold-adapted General descriptor for microorganisms, cultured or uncultured, that express traits enabling activity at low temperature.

Cryopegs Ancient (>100,000 years) lenses of liquid brine of marine origin, found in deep layers of Arctic permafrost at temperatures of −6 to −12°C.

Enzymes Proteins that catalyze chemical reactions which otherwise would occur only slowly if at all; extracellular enzymes are held near the surface of the cell or released into the environment.

Eutectic temperature Lowest temperature at which a mixture of salt and water can contain any liquid (about −55°C for seawater); below it, liquid water converts to solid (ice) and dissolved salts precipitate; eutectophile refers to a microbe living near the eutectic temperature in a natural (saline) ice formation.

Freezing point Temperature at which liquid water begins to convert to solid phase (ice); the freezing point of pure water (0°C) is lowered by the presence of impurities (salt, organics).

Lipid bilayer Critical component of the semipermeable membrane enclosing a microbial cell; when composed of unsaturated fatty acid-rich complexes, the lipid bilayer imparts greater flexibility to the membrane at low temperature.

Mesophilic Thermal descriptor for cultured members of the domain Bacteria or Archaea that reproduce at a minimal temperature of ~10°C, optimal temperature near 37°C, and maximal temperature of ~45°C.

Oligotrophic Descriptor for nutrient-poor environments, where nutrients refer to organic substrates utilizable by heterotrophic microbes.

Permafrost Perennially frozen soil or rock material, not subject to seasonal warming, found in polar regions.

Psychrophilic Thermal descriptor for cultured members of the domain Bacteria or Archaea that grow at a minimal temperature of 0°C or lower, optimal temperature of 15°C or lower, and maximal temperature of ~20°C (also stenopsychrophilic).

Psychrotolerant Thermal descriptor for cultured members of the domain Bacteria or Archaea that grow at a minimal temperature of 0°C or lower and maximal temperature above 20°C (also eurypsychrophilic).

Earth has not always been cold. Clear signs of the first glaciation period date to the middle of its history, at about 2.2 billion years ago. Since then, the planet has undergone epochs of warming and cooling, implying that cold-adapted microbes periodically faced extinction as a thermal class or else found refugia, most likely in a cool ($\leq 15^\circ\text{C}$) deep sea. Current global warming is again reducing the extent of cold, and especially frozen, habitats that arguably provided conditions for the evolution of today's cold-adapted microbes. More than at any time in the history of modern science, research on the extremophiles of cold environments is warranted. Motivations for such research have always included the desire to understand fundamental cellular and molecular aspects of cold adaptation, often centering on how or when a microbe produces lipid membranes flexible enough to transport and exchange solutes and ions with its environment or enzymes capable of catalyzing essential biochemical reactions in the rigidifying cold. There is also now a heightened sense of urgency to understand how microbes currently driving biogeochemical cycles in the cold may respond to environmental warming and thus impact existing food webs and carbon sequestration from the atmosphere. The further expectation that cold-adapted microbes and their products can be harnessed for societal needs, from bioremediation of cold environments to development of alternative energy sources through cold hydrolysis, drives applied research on the extremophiles of the cold. How microbes function or simply survive in frozen environments and unusual ice formations that approach the eutectic has become a central issue in the emerging field of Astrobiology. Most of the current targets for potential (or past) life in our solar system present us only with surfaces at extremely low temperatures, from a planetary-scale average on Mars of −55 (the eutectic for Earth's seawater) to −160°C on Europa, the ice-covered moon to Jupiter believed to harbor an ocean larger than ours.

Deming made changes in Sections "Text revisions to Earliest Observations and Terminology", "Exploration of the Cold Deep Sea", "Exploration of other Low Temperature Environments", "Influence of Astrobiology", "Molecular Basis for Cold Adaptation" and "Membrane Fluidity"; added new Figures 1 and 4 and updated "Further Reading" section.

This article is an update of J.W. Deming, Extremophiles: Cold Environments, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 147–158.

Discovery of Cold-Adapted Microbes

Earliest Observations and Terminology

The earliest known report of microbial life in a cold environment dates back to the fourth century BC and the writings of Greek philosopher Aristotle who made observations of what later proved to be photosynthetic Eukarya ("red algae") that turned snow to a reddish color. More than two millennia later in the 19th century (1887), the German scientist Forster described the ability of a bioluminescent bacterium, derived from fish preserved in the cold, to reproduce at 0°C. In the 20th century (1902), the term "psychrophile" for cold loving was introduced by Schmidt-Nielsen to describe such microorganisms.

Over the next 60 years, the term psychrophile continued to be in use to describe cold-adapted microbes according to the ability to reproduce in the cold, regardless of the upper temperature limit for growth. That limit, with few exceptions, fell above room temperature, thus overlapping with the thermal category of mesophiles. These microbes today are called psychrotolerant (or psychrotrophic), with the descriptor psychrophilic reserved for organisms that fit the more precise definition provided by the American marine microbiologist Morita (in 1975), based on cardinal growth temperatures: minimal temperature ($T_{\min}$) of 0°C or lower, optimal temperature (T_{opt}) of 15°C or lower, and maximal temperature ($T_{\max}$) of about 20°C (Fig. 1). By this definition, which provided much needed clarity at the time and remains in wide use today, the first true psychrophile was discovered by Tsiklinsky as part of a French expedition to Antarctica (1903–05). Another half-century would pass before the abundance and functional roles of true psychrophiles in cold environments would be appreciated. First, microbiologists had to learn about the sensitivity of cold-adapted microbes to room temperature (even to unchilled pipets) during isolation procedures. Eventually, after many enrichment studies using 4–6°C (convenient refrigerator temperature) and reports of predominantly psychrotolerant isolates, came the understanding that the temperature of initial enrichment influences the thermal nature of the resulting isolates: enrichments near the freezing point (e.g., at –1°C for marine samples) are more likely to yield psychrophilic than psychrotolerant bacteria.

Morita expected that future adjustments to his definition of psychrophily would be in the direction of lower cardinal temperatures, based on new isolates obtained by paying attention to detrimental (and influential) temperatures during isolation procedures. Such microbes with considerably lower cardinal growth temperatures, called extremely psychrophilic, have been cultured from the marine environment; for example, the Gammaproteobacteria *Psychromonas ingrahamii* ($T_{\min}$ = –12°C, T_{opt} = 5°C, $T_{\max}$ = 10°C) and *Colwellia psychrerythraea* strain 34H ($T_{\min}$ = –12°C, T_{opt} = 8°C, $T_{\max}$ = 18°C) from subzero Arctic sea ice and sediments, respectively. The current record holder for low-temperature growth, however, is *Planococcus halocryophilus* Or1 ($T_{\min}$ = –15°C, T_{opt} = 25°C, $T_{\max}$ = 37°C), a Gram-positive bacterium derived from permafrost at ambient temperature of –16°C. This organism categorizes as psychrotolerant, growing across an unusually wide temperature range of 52°C (from –15 to 37°C), consistent with its thermally dynamic environment. Measurements of microbial metabolic activity at extremely cold temperatures in natural ice formations (down to at least –20°C), where measuring an ambient reproductive rate is methodologically challenging, has led to introduction of the term eutectophile for the most cold-adapted microbes, living in ice near the eutectic temperature with only nanometer-scale films of liquid water available.

Because cardinal growth temperatures cannot fully capture the adaptability of a microorganism to its environment and are unavailable for the vast majority of microbes in nature that evade cultivation, the term psychrophilic (and psychrotolerant) remains most useful for categorizing cultured members of the domains of Bacteria and Archaea. Cold-adapted is used very generally to

Fig. 1 Idealized depiction of bacterial growth rate as a function of temperature (at atmospheric pressure) for a psychrophilic, psychrotolerant, and mesophilic microbe. The dashed line depicts the shift in response of a deep-sea psychrophile when grown under elevated hydrostatic pressure. The dotted vertical line indicates the freezing point of seawater.

describe microorganisms, cultured or uncultured, that express a recognizable adaptation to low temperature, while cold-active is often reserved for enzymes and viruses with catalytic or infective activity at low temperature. Other terms based on cardinal growth temperatures, particularly stenopsychrophilic and eurypsychrophilic (comparable in operational meaning to psychrophilic and psychrotolerant, respectively), attempt to recognize that psychrotolerant microbes are not simply tolerant of the cold (some mesophiles and thermophiles can tolerate the cold) but also adapted to it, in spite of higher T_{opt} and T_{max} for growth than psychrophiles.

What constitutes a cold temperature is also subject to perspective. Combining cardinal growth temperatures for psychrophiles and some key environmental temperatures yields the following set of descriptors. Moderately cold is 15 to 5°C; that is, from the upper T_{opt} for psychrophilic growth, which is also the average temperature of the surface of the Earth, down to the (upper) temperature of 80% of the biosphere. Cold is 5 to −2°C, the approximate freezing point of seawater, while very cold is below −2°C. Extremely cold is below −15°C, the current lowest T_{min} for microbial growth in culture and representative of the temperature of the Earth's near-million year-old permafrost in polar regions. Cold in the term cold adaptation remains broadly defined by any temperature 15°C or lower.

Exploration of the Cold Deep Sea

The cold deep sea, as the volumetrically dominant and most persistently cold environment on Earth (over geologic time), has provided an important natural laboratory for studying and advancing understanding of cold adaptation in the microbial realm. Although its temperature is always above the freezing point of seawater and thus not as thermally extreme as most frozen environments, the cold deep sea is considered extreme for other reasons: its elevated hydrostatic pressure, which increases linearly at 10 atm (=1 MPa) per 100 m increase in water depth, and its generally oligotrophic state. The search for psychrophiles in the cold deep sea has often been coupled with the search for barophiles (also known as piezophiles), pressure-adapted microbes that grow more rapidly under elevated hydrostatic pressures than at atmospheric pressure when adequate nutrients in the form of organic substrates are available. The focus of these searches has usually been the heterotrophic bacteria.

Scientific exploration of oceanic life, in general, began with a series of deep-sea expeditions at the end of the nineteenth century (study of the productive surface layers and sea ice would come later). Until the discovery of deep-sea hydrothermal vents in the latter half of the twentieth century (vent-supported life was first reported in 1977), the deep ocean was understood to be uniformly cold, the temperature not exceeding about 5°C (except in the deep Mediterranean and Sulu seas where temperatures reach about 15°C). Yet, early expeditions had no facilities for incubating samples shipboard at such low temperature. The first opportunities to discover cold-adapted microbes from the vast, cold deep sea were thus thwarted by lack of refrigeration. Remarkably, the early French explorer Certes was able to test for pressure-adapted microbes from the deep sea in the 1880s, even if cold adaptation was beyond reach.

More than a half-century later, American marine microbiologist ZoBell began the study of deep-sea microbes under both in situ pressure and temperature, documenting with Morita in 1957 the first psychrophilic barophiles. Although these cultures were lost to future study, similar efforts by several groups beginning from the 1970s eventually yielded sizeable culture collections of psychrophilic barophiles; indeed, all barophiles cultured from the cold deep sea are also psychrophilic. The synergistic effects of temperature and pressure on microbial growth (or other activities) have not been fully explored, but for some psychrophilic bacteria their cardinal growth temperatures can be shifted upward by incubating under higher pressure (Fig. 1). When the growth responses of deep-sea bacteria have been examined according to a matrix of three parameters – temperature, pressure, and salinity – salt concentration is also observed to shift cardinal growth temperatures, though the direction of the shift is variable and strain-dependent. Microbiological exploration of the cold deep sea has thus raised general awareness that cold adaptation must be understood in relation to other parameters and not exclusively to temperature.

Not least of other parameters is the concentration of available energy sources or organic substrates in the case of the heterotroph. For heterotrophic psychrophilic barophiles the barophilic trait depends upon available substrate concentration: at low substrate concentrations, growth rate is similar under both atmospheric and elevated pressures (barotolerant, within the pressure range for growth), while at high substrate concentrations, growth rate is higher under elevated pressures than at atmospheric pressure (barophilic). When substrates are in adequate supply in the cold deep sea, for example, from the hydrolysis of freshly deposited organic detritus, psychrophilic barophiles will outcompete other cold-adapted microbes that may be present. Genetic work with pressure-adapted psychrophiles indicates that membrane proteins involved in substrate uptake are upregulated under elevated pressures when provided with sufficient substrate.

Somewhat analogous work with marine psychrophiles from shallow cold waters, considering only temperature and substrate concentration, indicates that the lower the temperature, the higher the required substrate concentration to achieve a comparable growth (or oxygen respiration) rate. Low temperature or viscosity-driven reduction of the diffusive flux of various solutes to the cell contributes to but is insufficient to account for this increase in the required substrate concentration threshold. Resolving the issue is important to understanding why, at least at times, the microbial role in biogeochemical cycles of surface polar waters appears limited until sufficient organic solutes accumulate. Although gene expression work that may help to explain this phenomenon remains to be conducted, the available whole-genome analyses of heterotrophic psychrophiles reveal a capacity to store substrate reserves intracellularly, a potential means around the problem for the individual cell. Also awaiting a gene expression-based explanation is the repeated observation that cold temperature favors higher bacterial growth efficiency: a greater fraction of the organic carbon consumed in the cold goes to new biomass (gain to the food chain) than to respiration (loss as carbon dioxide).

Warming temperatures in polar waters are thus expected to shift the role of cold-adapted microbes in the cycling of organic carbon to increased remineralization to carbon dioxide.

Exploration of Other Low-Temperature Environments

Many other cold environments have been explored over the past several decades for cold-adapted microbes. Moderately cold to cold environments include a wide range of aquatic and sedimentary environments, both marine and freshwater (rivers, lakes, and subsurface aquifers), terrestrial soil environments of varying degrees of desiccation, and numerous surfaces that support microbial biofilms, from moist rocks in caves and mines to fluid-bathed tissues of vertebrate and invertebrate animals that live in the cold. Unlike the cold deep sea, many of these environments experience fluctuating temperatures (and other parameters) on a seasonal and diurnal basis. Exceptions with stably cold temperatures include animal-associated microbial environments, where the animal host spends its life history in cold water, as well as the many deep subglacial lakes of Antarctica (close to 400 have been discovered) with stable temperatures just above the freezing point, given separation from the lower atmosphere and solar radiation by kilometers of glacial ice. With the possible exception of subglacial lakes, where the temperature requirements of microbial inhabitants have not been addressed in live culture, all of these cold environments have in common their successful colonization by cold-adapted microbes, which then play active if not dominant roles in cycling the inorganic and organic materials within them. Based on classical chemostat studies pitting cold-adapted microbes with different cardinal growth temperatures against each other at constant cold temperature, the more psychrophilic organisms are the dominant players.

In contrast are the environments that experience very cold to extremely cold temperatures, including the upper atmosphere, where viable microbes have been found associated with microscopic particles, and the major types of ice formations on Earth – freshwater snow and glacial ice (formed from long-term compaction of snow), lake and river ice, polar and subpolar sea ice, and frozen soils. Except for sea ice (see below) and possibly lake ice (less well studied), frozen environments in general can be viewed as preserving an often cosmopolitan suite of microbes, largely inactive in the cold, rather than as actively colonized by cold-adapted microbes with all the attendant successional and adaptive responses. At extremely cold temperatures, the primary limitation to the latter scenario is the absence of sufficient water in the liquid phase. All ice formations on Earth derive from source waters containing impurities of one kind or another that depress the freezing point (especially inorganic salts), so they retain at least some liquid water. Only those that may drop below their eutectic temperature, for example, high-altitude glacial ice on Antarctica, become completely desiccated.

Some of these frozen environments experience seasonal and/or diurnal temperature swings, which intermittently relieve the limitation of insufficient liquid water. They can then support highly productive microbial ecosystems. On the surface of glacial ice, for example, wind-deposited dust called cryoconite absorbs solar radiation and melts small holes into the ice, where liquid and nutritional resources can be sufficient to allow cold-adapted microbes to flourish. Another example is sea ice, which during spring and summer seasons, with near-continuous sunlight and seawater flushing its base with nutrients, develops algal and microbial communities visible to the naked eye as strongly discolored ice (Fig. 2). These communities contribute 25% or more of total primary production in the Arctic with consequent effects on secondary production (the transformation and consumption of this biomass) and higher trophic levels. Sea ice (like lake and river ice), however, is not a stable environment, melting by late summer before reforming in fall. An exception is multiyear sea ice in the Arctic Ocean that until recently could survive 8–10 melting seasons before circulating out of the Arctic into warmer (ice-melting) Atlantic waters. Climate-driven declines in multiyear (and first-year) sea ice, which had been averaging about 10% per decade since satellite coverage began in the 1970s, recently accelerated beyond all model predictions. This particular frozen environment may soon represent a lost opportunity for the study of cold adaptation.

The upper layers of soil in alpine and polar regions also experience regular and wide fluctuations in temperature seasonally, from warm ($>20^{\circ}\text{C}$) to extremely cold, as well as climate-driven warming. Even during moderately cold periods, microbial activity increases such that the environment becomes a source of greenhouse gases, like carbon dioxide and methane, rather than a sink. In alpine soils, an insulating snow cover promotes substantial microbial activity through the winter. The deeper frozen layers (>50 m) of polar soils removed from atmospheric and solar influences, however, have been permanently frozen (permafrost) in the temperature range of -10 to -12°C for close to a million years in some Siberian locations. The typical diversity of soil microbes that have been recovered in culture from permafrost, including aerobes, anaerobes, heterotrophs, sulfate reducers, and methanogens, may represent some of the oldest viable forms available to study. Wedged between deep layers of permafrost are cryopegs, recently discovered multimeter-scale lenses of very old unfrozen water kept liquid by high salt concentration. Available isotopic and other evidence indicates an ancient marine source for these brines and active microbial and viral communities within them, despite total darkness and anoxia. The physical separation of these communities from contemporary ecosystems over geologic time makes them promising sites for the study of microbial evolution under extreme conditions that include very cold temperatures.

In the upper atmosphere, in high-altitude glacial ice and snow that covers Greenland and Antarctica, and in Arctic winter sea ice and its overlying snow cover, microbes experience extremely cold temperatures, sometimes approaching or reaching the eutectic of -55°C (for seawater). The thermal gradients inherent to glacial and sea-ice environments (Fig. 2) provide natural laboratories to examine the question of the lower temperature limits for microbial growth, activity, and survival. To date, studies of such environments and of artificially produced ices at extreme temperatures suggest that cellular reproduction may be limited to about -20°C , metabolic activity to about -40°C , and survival to the lowest temperatures yet to be tested (-196°C in liquid nitrogen). These general guidelines, however, are subject to change, especially as the field of Astrobiology stimulates increased experimentation under extremely cold conditions.

Fig. 2 Schematic depiction of some characteristics of sea ice. At left are vertical gradients, in temperature and in salinity of liquid inclusions, that develop in winter as temperature of the overlying atmosphere drops but underlying seawater remains near freezing point. Middle panels depict relative size of brine pores in a very cold section of ice vs. bottom ice, where larger channels flushed by seawater will support an ice-algal bloom in spring. At right is an enlarged schematic of very cold brine at the juncture of three ice crystals, depicting microbes embedded in a gelatinous matrix of exopolymers, brine, and organic substrates concentrated in the interior, and extracellular enzymes hydrolyzing the substrates. Also shown are proposed cold-active viral enzymes at work, enabling successful infection and viral reproduction, host lysis, and release of free DNA and new viruses, potential agents of horizontal gene transfer.

Early in the study of this varied array of low-temperature environments, a general paradigm emerged: stably cold environments tend to support a greater (culturable) community of psychrophilic microbes, while those with temperatures that fluctuate, especially above the T_{max} of psychrophiles, tend to support a greater community of psychrotolerant (eurypsychrophilic) microbes. The implication was that psychrophily requires a stably cold environment to evolve. Although this paradigm appeals to common sense, much of the early data supporting it relied upon enrichment temperatures that would have favored psychrotolerant microbes. When more stringent enrichment conditions are used (e.g., -1°C for saline environments), temperature-fluctuating environments that previously yielded mainly psychrotolerant isolates yield a predominance of psychrophiles instead. Psychrophiles have also been observed to reestablish dominance in an environment in a relatively short period of time (days), once fluctuating temperatures have stabilized at a cold temperature. Furthermore, the sea-ice environment, which has always consistently yielded greater numbers of psychrophiles, is an ephemeral one, with inhabitants released during the summer melt period to seawater that then warms under 24 h solar radiation. From initial encasement during ice formation in fall through the winter, spring and summer seasons, sea-ice microbes can experience a temperature fluctuation of more than 40°C , from -35 in winter to 6°C (and higher) in melt water. The corresponding fluctuations in other parameters, especially salt concentration (Fig. 2), add osmotic and other stresses to the thermal swing. Although psychrophiles have long been considered the more sensitive of cold-adapted microbes, in large part because some express narrow temperature ranges for growth (unlike those shown in Fig. 1), environmental robustness is a matter of perspective influenced by considering other parameters. What constitutes an ideal habitat for cold adaptation needs to be reconsidered.

Influence of Astrobiology

The ongoing and planned exploration of other bodies in our solar system for evidence of past or present life has opened a new chapter in the history of studying cold-adapted extremophiles. Even the extremely cold environments of Earth are thermally moderate relative to the extraterrestrial sites targeted for exploration. For example, the average surface temperature of the desiccated soils on Mars is about -55°C , coincidentally the eutectic temperature for Earth's seawater. Where the surface temperature is warmer, not even nanometer-scale films of liquid water are available and radiation intensity (in the absence of a protective atmosphere as on Earth) would be prohibitive. The average temperature of the deeply frozen surface of Europa, the Jovian moon that harbors beneath its ice cover a global ocean larger than Earth's, is about -160°C . On Enceladus, the Saturnian moon recently shown to release

plumes of water containing carbon and nitrogen compounds provocative of life, the average surface temperature is -201°C . Such extremely cold ice formations are not found on Earth, invoking the need to study forms of ice generated in the laboratory. Initial studies of the reactions of a known psychrophile to flash freezing, as might be experienced when oceanic waters on Europa and Enceladus rise through cracks of an extremely cold ice cover, have pointed to the importance of organic (sugar-rich) exopolymers in buffering cells against damage from the freezing process. Because the presence of exopolymers in saline ice formations are also known to alter the microstructure of the ice in readily detectable ways, similar effects in extraterrestrial ices may constitute a biosignature for life.

Although space missions have accessed only extremely cold surfaces (as on Mars), the subsurface environments of Mars, Europa and Enceladus, hidden from damaging radiation, hold greater promise for life. They are expected to be more moderate in temperature, favoring liquid water (perhaps in analogy to the brine layers of deeply buried permafrost), and to offer potential energy sources for chemolithotrophic life forms, for example, via the exothermic water-rock reaction known as serpentinization. In Earth's deep ocean at a mid-Atlantic site called Lost City, serpentinization is known to yield hydrogen and methane in support of luxurious archaeal biofilms and mats. The study of cold-adapted Archaea and chemolithotrophs in general remains in its infancy, relative to the heterotrophic bacteria.

Evolution of Cold Adaptation

Glaciation Periods on Earth

The temperature of the early Earth and its ocean is actively debated, but marine geological evidence points to a very hydrothermally active and thus warm ocean. The first hypothesized period of planetary-scale chilling or glaciation does not occur until about half-way through Earth's history at 2.2 billion years ago during the Proterozoic era. Less than a billion years ago, Earth is believed to have experienced a severe freezing episode resulting in what has been called "Snowball Earth". Since then, the planet has experienced a series of glaciation events, not always global in scale, eventually leading to the glacial/interglacial periods of recent Earth history. Their periodicity is estimated in tens of thousands of years. In between each major ice age, the planet is believed to have been completely free of ice with an average surface temperature above that permissive of a psychrophilic lifestyle.

Unless the deep sea remained sufficiently cold to provide refuge to a stock of psychrophiles, a difficult hypothesis to test, psychrophilic microbes likely evolved more than once during Earth's history. The implication is that the evolutionary steps between psychrotolerance and psychrophily must be accommodated by the time available between glaciation periods. In addition to vertical gene transfer from an ancestor (inherited beneficial gene mutations), horizontal gene transfer (e.g., mediated by viruses or free DNA) may have played important roles in achieving these steps. Leading the way to tests of this hypothesis are phylogenetic analyses of extant microbes, cultured and uncultured, comparative genomic evaluations of psychrophiles and other thermal classes of microbes, and experimentation with horizontal gene transfer in the cold.

Phylogeny of Cold Adaptation

The now classic 16S rRNA gene-sequencing approach to deducing relationships among organisms yields a universal tree of life on which known psychrophilic and psychrotolerant microbes can be located. Use of a phylogenetic tree originally designed to highlight hyperthermophilic genera of Bacteria and Archaea (those that grow at 90°C or higher) for this purpose emphasizes the late arrival of cold adaptation among extant organisms (Fig. 3). It also indicates the slightly deeper branching of groups containing only psychrotolerant members, reinforcing the expectation that psychrophiles evolved from psychrotolerant strains.

Most of the major branches within the domain of Bacteria, except those unique to thermophiles, contain psychrophilic members, including all five groups of the *Proteobacteria*, aerobes and anaerobes alike, the *Cytophaga-Flavobacteria*, the *Cyanobacteria*, and the Gram-positive bacteria. Some genera of the *gamma*proteobacteria, in particular *Moritella* and *Colwellia*, are comprised mainly or exclusively of psychrophiles. The Green nonsulfur bacteria, however, contain only psychrotolerant isolates so far.

In the domain of Archaea, only a single culture-authenticated psychrophile is known, the methanogen *Methanogenium frigidum*, isolated from an Antarctic lake. Its position within the archaeal domain of the tree also indicates a later evolutionary arrival (Fig. 3). The marine Crenarchaeota have a somewhat earlier branching position. Members of this archaeal group often dominate numerically in the cold deep sea and occur in many of the polar waters and sediments that have been examined, but only one of their members has been brought into culture (from an aquarium sample enriched at room temperature). It is not cold-adapted. A well-studied crenarchaeal symbiosis with a sponge host that dwells in cold waters clearly suggests cold adaptation, but whether psychrophilic or psychrotolerant awaits a cultured isolate. Because the marine Crenarchaeota that inhabit the cold deep sea are believed to be involved in the nitrogen cycle, especially the process of nitrification (microbial oxidation of ammonia to nitrite and nitrate) which generates the inorganic nitrogen required by primary producers in surface waters, they are targets of intensive study.

Given that the study of cold adaptation in the microbial realm has historically centered on heterotrophic bacteria, in large part because these organisms are more readily brought into culture than chemolithotrophs or Archaea in general, conclusions from the depicted phylogenetic tree (Fig. 3) should be drawn with caution. As more microbes are brought into culture and shown to be cold-adapted, the branching patterns evident today may change. Stable isotope (and other) probing techniques that allow recognition of microbial activity under different temperatures in the absence of cultivation, yet coupled to a sequencing identification, may also bring new information to the tree, as may targeted studies using transcriptomics, proteomics, and metabolomics.

Fig. 3 Universal phylogenetic tree of life based on 16S rRNA sequences, emphasizing the domains of Bacteria and Archaea. Orange branches indicate hyperthermophiles that grow at $\geq 90^{\circ}\text{C}$; purple branches, groups that contain known (cultured) psychrotolerant strains; and blue branches, groups that contain known (cultured) psychrophiles. Note that the (uncultured) marine Crenarchaeota are colored purple because degree of cold adaptation is not known.

Genetic Mechanisms

Genetic mutation as a means to cold adaptation is evident from studies of the molecular interactions inferring enzymes with catalytic ability in the cold and in comparative analyses of whole-genome sequences from related organisms with different cardinal growth temperatures. In the former case, site-directed mutagenesis and related approaches indicate that, depending on the enzyme and often its size, anywhere from a single amino acid change to numerous amino acid substitutions or chemical alterations can explain the gain (or loss) of cold activity. In the latter case, and despite an oft-cited idea that only a critical subset of an organism's enzymes need be cold-active for it to function as a psychrophile, results of comparative genome studies for both Archaea and Bacteria suggest otherwise. Significant amino acid replacements were observed in over 1000 genome-deduced proteins from the psychrophilic methanogen, *M. frigidum*, relative to proteins from other methanogens covering a range of temperature growth optima, from 15 to 98°C . When the whole proteome of *C. psychrerythraea* 34H and three-dimensional architectures of its proteins were compared to nearest mesophilic neighbors with available genome sequences, the same general observation was made. In both cases, the interactions and locations of polar and charged amino acids (in particular serine, histidine, glutamine, and threonine) in protein tertiary structures appeared influential in imparting psychrophily.

In other analyses of the whole genomes from the several psychrophiles that have been sequenced so far, specific proteins and other features known from previous culture work to impart cold adaptation (discussed below) have been documented. A new genomic finding, not widely evident from prior culture work, is the prevalence of virally delivered genes in psychrophiles along with the presence of prophage (viruses residing benignly in the bacterial genome and thus implicated in gene transfer). That virally mediated horizontal gene transfer has played an important role in the evolution of psychrophily appears inescapable, although other forms of gene transfer also need to be considered (transformation by direct uptake of free DNA and plasmid exchange by conjugation between cells; Fig. 4), particularly since the transfer of plasmid DNA via conjugation between mesophilic and psychrophilic bacteria has been demonstrated.

In the same time frame that genomic analyses of psychrophiles have become available, the study of cold-active virus–host systems in culture has been renewed. While work over a half-century ago had documented infectivity at 0°C , the environmental and evolutionary implications had only rarely been pursued. Recently, several promising cold-active virus–host systems have been obtained by a number of researchers and the lower (known) temperature limit for infectivity has been pushed to -12°C (and 16% salt) in simulated sea-ice brines. The goal of demonstrating active horizontal gene transfer under realistic environmental conditions, whether or not mediated by viruses, as means to evolve cold adaptation remains for the future.

Molecular Basis for Cold Adaptation

As the temperature of an aqueous solution decreases, for example, from 37 to 0°C , its viscosity more than doubles, slowing solute diffusion rates, while chemical reaction rates (also influenced by viscosity) decrease exponentially. The cytoplasmic membranes and

Fig. 4 Simplified schematic of a bacterial cell depicting some of the known components and processes linked to cold adaptation (see text).

enzymes of mesophilic microbes tend to rigidify under these conditions and lose function. Protein folding is impaired and nucleic acids assume secondary or super-coiled structures that interfere with their proscribed activities. A hallmark of microbial cold adaptation at the molecular level is thus to retain sufficient flexibility in its macromolecules such that essential functions can go forward in spite of the challenging effects of low temperatures. When arguably nonessential functions, for example, motility, can also go forward, the microbe becomes even more competitive in the cold. The lower temperature limit for bacterial motility, -13°C (in a glycerol solution), is held by an extreme psychrophile, *C. psychrerythraea* 34H, while recent work with a digital holographic microscope has revealed motility in natural sea-ice brine communities at -4°C , the lowest temperature tested. Enough direct research on psychrophiles and comparative studies of psychrotolerant and mesophilic bacteria has been accomplished in recent decades to identify key components and aspects of a cell that impart cold adaptation (Fig. 4).

Membrane Fluidity

The cellular membranes of cold-adapted microbes must remain flexible enough under rigidifying temperatures to facilitate their essential functions in the transport of nutrients and metabolic byproducts and the exchange of ions and solutes critical to maintaining intracellular integrity. The cold-adapted cell accomplishes this feat by fine-tuning the composition of its membrane lipid bilayer (Fig. 4), introducing steric hindrances that change the packing order of the lipids or reduce interactions between them and other membrane components. The genome must encode the ability to produce a flexible membrane in the first place (adaptation), as well as to adjust membrane components on the short-term (acclimation). The list of specific alterations known to enhance flexibility in the cold is extensive, if sometimes strain-specific, but typically includes producing a higher content of unsaturated (fewer double bonds between carbon atoms), polyunsaturated, and branched and/or cyclic fatty acids in response to cold. In some cases, shortening the length of the fatty acid can enhance flexibility, while in others, changing the content or size of the lipid head groups helps. Genes for enzymes involved in polyunsaturated fatty acid (PUFA) synthesis are clearly present in psychrophilic genomes, although without tests of their cold-active nature, such findings are not definitive for cold adaptation (some mesophiles also contain them).

Other components of the lipid bilayer include membrane proteins and carotenoid pigments. How membrane proteins interact with lipids affects both the active and passive permeability of the membrane, important for controlling the exchange of ions and organic solutes (Fig. 4). The genomes of *C. psychrerythraea* 34H and *P. halocryophilus* Or1, for example, contain numerous gene families involved in the transport of solutes, low-molecular-weight organic compounds (often sugars or amino acids and their derivatives) that accumulate to high intracellular levels under osmotic stress, and are compatible with the metabolism of the cell. They help to maintain cellular volume and turgor pressure and protect intracellular macromolecules in the face of changing salt

concentrations exterior to the cell, as occurs in sea-ice brines when the temperature drops (Fig. 3). Recent work with both psychrophilic and psychrotolerant isolates in culture, and with natural sea-ice brine communities, indicates widespread reliance on compatible solutes by cold-adapted bacteria. The cold-adapted membrane thus needs to be flexible, especially in very cold environments, to permit the uptake (and release) of compatible solutes as well as energy-yielding substrates, yet impermeable enough to prevent excessive passive exchange; adjusting the protein components of membranes can help. The sensitivity of some membrane proteins to temperature-driven conformational changes appears to provide a thermal sensor that results in the upregulation of genes involved in subsequent membrane adjustments, making life in a temperature gradient imminently feasible. As temperatures approach T_{max} for growth, cold-adapted microbes must also be able to keep their membranes sufficiently stable (inflexible) to avoid cell leakage and death by lysis. In some cases, adjusting pigment content appears to accomplish this goal.

Cold-Active Enzymes

The exponential drop in chemical reaction rates brought on by decreasing temperature highlights the impressive evolutionary development of all manner of enzymes with high catalytic activity in the cold. Complementing the known membrane adjustments to achieve flexibility in the cold are those expressed by cold-active enzymes, including essential intracellular enzymes required for nucleic acid and protein synthesis in the cell, membrane permeases for active solute transport and alteration, and extracellular enzymes released to perform hydrolytic functions in the environment (Fig. 4). For cold environments that experience strong UV radiation, the microbial production of enzymes that scavenge reactive oxidative (chemical) species may also be considered essential. As with achieving a more flexible membrane against the cold, achieving high enzymatic activity at low temperature involves creating greater molecular flexibility than that observed in enzymes active at warm temperatures. It also involves trade-offs; although not a firm rule, for many cold-active enzymes the very traits that impart cold activity also make them unstable at higher temperature. Unlike membrane adjustments, enzyme adaptations over an evolutionary time scale appear more relevant to cold activity than means for short-term acclimation. The strategies for increased flexibility of an enzyme leading to cold activity are numerous but not uniform. In some cases, increased flexibility is linked to a shift in primary structure (amino acid composition) of the entire protein, while in others only direct adjustments to the catalytic site of the three-dimensional macromolecule are involved. For some enzymes, including those released from the cell to perform hydrolytic functions in the environment, adjustments to flexibility are detected in the regions of the protein exposed to the solvent. Keeping an exterior shape firm as temperature drops can translate to keeping a more protected catalytic site flexible.

Considering the interface between the exterior shape of an enzyme and the solvent raises the need to consider enzyme interactions with other components in the environment, independently of the cell. For example, the extracellular polysaccharides released by *C. psychrerythraea* 34H have been observed to stabilize an extracellular protease (that it also produces) against thermal denaturation. The effective work of extracellular enzymes in the cold, for example to hydrolyze organic substrates to a size that can be transported into the cell, may be an important trait of heterotrophic psychrophiles. Over half of the enzymes assigned to the degradation of proteins and peptides in the *C. psychrerythraea* genome are predicted to be localized external to the cytoplasm, among the highest percentage in any completed genome (from all thermal classes). The successful infection (and reproduction) of a virus in this same psychrophile at very cold temperatures (-10 to -13°C) suggests that at least some viruses in cold environments may carry highly cold-active lysozymes for penetrating the cell membrane (Figs. 3 and 4).

In spite of multiple strategies to achieve enough flexibility for catalytic activity in the cold, intracellularly or extracellularly, some common trends have emerged from enzyme studies regarding specific chemical modifications required to reduce the strength or number of otherwise stabilizing factors for a protein. These include reducing ion pairs, hydrogen bonds and hydrophobic interactions, inter-subunit interactions, cofactor binding, and proline and arginine content. Increasing exposure of apolar residues to the solvent, accessibility to the active site, and the clustering of glycine residues also pertain. Such trends provide means to search available (and future) genomes for signs of cold adaptation. They also provide blueprints to identify or engineer proteins for applied uses in the cold, many of which have been identified by the food, detergent, and biotechnology industries, by those seeking means to remediate the contamination of cold environments, and by start-up companies interested in the possible production of cost-effective fossil fuels that take advantage of enzymatic hydrolysis in the cold. A promising recent example is the discovery of potentially novel hydroxylases for alkane, a major component of crude oil, which could be scored as cold-active based on amino acid preferences and regions of increased flexibility typical of psychrophiles.

Cold-Shock Proteins

For the cold-adapted microbe, all nucleic acids and proteins involved in maintaining (if not synthesizing), transcribing, and translating genetic information intracellularly must be able to function in the cold. In some cases, this feat is thought to be accomplished not by primary alteration of the macromolecule itself, as already described, but by production of specific proteins that bind to them, presumably enabling proper conformation and flexibility, including required periods of destabilization. The production of cold-shock proteins to serve a similar function when mesophiles are subjected to a temperature downshift is well studied, but less is known about related responses of cold-adapted microbes to downshifts in temperature or to continuous life in the cold. Available information on psychrotolerant bacteria indicates that large numbers of cold-shock proteins (related to those in mesophiles) are always present and that production of cold-acclimation proteins is continuous in the cold, as is the expression of housekeeping genes (for basic cellular functions). By contrast, the mesophile *Escherichia coli* carries few cold-shock proteins prior to

cold shock, but a temperature downshift immediately results in repression of critical housekeeping genes and induction of cold-shock (but not cold-acclimation) proteins, which is transient.

The continuous production of a variety of binding proteins to maintain proper conformation, flexibility, and function of major macromolecules thus appears to be an important trait of cold adaptation (Fig. 4). Although work with live psychrophiles is needed, genomic sequence data support this idea; for example, the genome of *C. psychrerythraea* 34H encodes for multiple common cold-shock proteins. Furthermore, the genetic acquisition of cold-shock proteins may not require the longer term evolutionary process of vertical inheritance but may be facilitated by horizontal gene transfer. Genes for cold-shock proteins known only from the domain of Bacteria have been observed upon genomic sequencing of an uncultured population of marine Crenarchaeota from cold Antarctic waters.

Cryoprotectants and Exopolymers

In very cold environments, the cellular membranes of resident microbes are subject not only to rigidity but also to physical damage from ice-crystal formation during the freezing process. Some cold-adapted microbes are known to produce and release specific proteins that help to control the formation of ice crystals (Fig. 4), including ice-nucleating proteins (that provide a template for crystal formation away from the cell) and antifreeze proteins that inhibit ice nucleation by dropping the freezing point or repressing the recrystallization of ice. The rate of freezing experienced by the cell also influences the degree of damage, with faster rates limiting the damage. Natural ice formations on Earth freeze slowly (producing ice crystals) relative to the vitrification process, whereby the liquid phase converts directly to solid without ice-crystal formation. When microbial cultures are vitrified in the laboratory (using liquid nitrogen at -196°C), their cell membranes remain intact with no morphological sign of damage. When vitrified in the presence of sugars, the likelihood of recovering them in culture after thawing increases.

Small molecular weight sugars (like glycerol) have long been used as cryoprotectants in the deep-freeze (-80°C) storage of microbes, presumably providing a buffer between cells and ice crystals. Newly discovered, however, is the overproduction of complex extracellular polysaccharides by cold-adapted bacteria, both psychrophilic and psychrotolerant, when subjected to increasingly cold temperatures, especially below the freezing point. Sea ice through its seasonal lifetime is also recently known to harbor high concentrations of sugar-based exopolymers in its liquid brine inclusions (Fig. 3). These exopolymers, produced copiously not only by sea-ice algae but also by ice-encased bacteria, are understood to serve as natural cryoprotectants not only against potential ice-crystal damage but also by further depressing the freezing point such that more liquid water remains available within the ice matrix. In this regard, cellular coatings of exopolymers (Fig. 4), or exopolymers available in the environment, are believed to provide a hydrated shell that helps to buffer the cell against the osmotic stress of high salt concentrations in winter sea-ice brines (Fig. 3). Along with the possible stabilization of extracellular enzymes, this myriad of functions makes exopolymers a cold-adaptive trait worth examining in more detail. The organization of genes for exopolymers on the genome of the psychrophilic bacterium *Psychroflexus torques*, for example, suggests that they may be the result of a series of lateral gene transfer events.

Conclusion: A Model Habitat for Cold Adaptation

Considering that the ocean represents the bulk of Earth's cold biosphere, today and in the past, the annual freezing of its surface waters in polar regions takes on special significance as an important planetary driver of cold adaptation. Astronomical numbers of bacteria (10^5 in a single milliliter of seawater) pass through this frozen gauntlet annually, and over extended periods in geological time. Microbes that experience a winter in sea ice are subjected to the linked stressors of increasingly cold temperature and high brine salinity as shrinking pore space further concentrates all impurities in the source seawater, including microbes (Fig. 2). This concentrating factor brings microbes into close proximity to each other, as verified by microscopic observations of DNA-stained cells in unmelted ice, in a liquid environment of abundant low- and high-molecular-weight organic compounds, including complex exopolymers that serve many positive functions for the trapped cells. Model calculations and observed concentrations in melted sea ice indicate that agents of lateral gene transfer (free DNA and viruses) also surround the encased cells (Fig. 2). The virus-bacteria contact rate in a winter sea-ice brine may be as much as 600 times higher than in underlying seawater. Active virally mediated gene transfer has not yet been demonstrated, but the sea-ice environment would appear to favor it.

Even if horizontal gene transfer is not operative in sea ice, the vertical inheritance of genes for cold adaptation must be a regular occurrence. The habitat of *P. ingrahamii*, one of the most extremely psychrophilic bacteria on record (shown to reproduce at -12°C), is sea ice. Isolates of *C. psychrerythraea* (strain 34H also grows at -12°C) are readily cultured from sea ice. Virtually all of the canonical molecular traits of cold adaptation, along with some new ones, have been documented in the test tube or by genome analyses of such sea-ice psychrophiles. Rather than a stably cold environment, the key to the evolution of cold adaptation may be repeated exposure to the extreme cold and brine of sea ice, selecting for robustness in the face of multiple insults, including future ones like hydrostatic pressure. That salt-heavy water masses form in polar oceans actively growing sea ice and then sink to fill the cold deep ocean over time points to the concept of a cold refuge for cold-adapted bacteria during interglacial times when ice as an evolutionary driver was nonexistent, as we may witness again in this century.

Glossary

Arid region Region on the earth's surface where the ratio of the mean annual precipitation to the mean annual potential evapotranspiration is less than 1; divided into the hyperarid, arid, semiarid, and subhumid zones.

Arid zone Region of the earth where the ratio of the annual precipitation to the annual potential evapotranspiration is between 0.03 and 0.20.

Biogeography The study of the distribution of organisms across geographical regions and the factors leading to observed distributions.

Chasmoendolithic habitat Lithic habitat consisting of the cracks and fissures in the rock, with more or less direct connection to the surface.

Compatible solute Low-molecular-weight organic compounds that can serve to lower the osmotic potential of a cell while maintaining cellular and molecular integrity.

Cryptoendolithic habitat Lithic habitat consisting of the naturally occurring pore spaces within the rock, usually only indirectly connected to the surface.

Deliquescence Process by which a substance absorbs water vapor from the air in sufficient quantities that it dissolves in the absorbed water.

Epilithic habitat Lithic habitat consisting of the upper exposed surface of a rock or stone.

Euendolithic habitat Lithic habitat consisting of holes and pits created by the metabolic activity of the microbial community.

Hyperarid zone Region of the earth where the ratio of precipitation to potential evapotranspiration is less than 0.03.

Hypolithic habitat Lithic habitat consisting of the lower surface of a stone in association with adherent soil particles.

Lithopanspermia Hypothesis suggesting that life can be transferred from planet to planet by means of rocks expelled from planetary surfaces through the force of meteorite impacts.

Perilithic habitat Lithic habitat consisting of the sides of a stone below the soil surface; distinguished from the hypolithic habitat on the lower surface of the stone.

Water activity (a_w) A measure of the concentration of water in a solution, as modified by the type of solutes present in the solution.

Water potential (ψ) A measure of the potential energy in a unit mass of water.

Nomenclature

ETP annual potential evapotranspiration

P annual precipitation

Defining Statement

This article summarizes the current state of knowledge concerning the microbial communities inhabiting arid regions, with an emphasis on lithic environments. The constraints put on these communities by their dry environment and their adaptations to survive the desiccated state are also addressed.

Introduction

It can be argued that dry environments present one of the most extreme set of conditions faced by microorganisms. The cell must be able to withstand the specific biochemical stresses created by the lack of water; also, it may be called upon to withstand a variety of other environmental insults – exposure to high levels of UV radiation, for example, or elevated temperatures during periods when its

[☆]*Change History:* July 2016. James A. Nienow added sections on biogeography of desert microorganisms and the relevance of desert organisms to astrobiology; made small changes to the rest of the text; added a new Figure, the terms biogeography and lithopanspermia to the glossary, citations, including citations to investigations published since 2009; and updated reference section.

This article is an update of J.A. Nienow, Extremophiles: Dry Environments (including Cryptoendoliths), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 159–173.

metabolic activity has been reduced to minimal levels by the same lack of water. On one level, then, it is surprising that any cells possess the required set of adaptations. Yet, when one considers the obvious selective advantages conferred by these adaptations in the 30% of the world not covered by liquid water, perhaps it is not so surprising after all. As will be seen, there are a variety of ways to cope with dry environments and a diversity of microorganisms employing them.

Before proceeding, it may be worthwhile to spend some time discussing what constitutes a dry environment. Clearly, the concept includes some mechanism leading to a reduction in the liquid water content of the cell. In general, the reduction of liquid water can be achieved either by freezing the cell or by the net movement of water out of the cell. Freezing conditions, then, in the broadest sense, constitute a form of dry environment. However, the freezing process involves its own set of biochemical stresses, which are not necessarily related to the lack of liquid water, and, therefore, will not be treated further; interested readers are directed to the review by Crowe and Crowe (2002). Instead, the discussion will revolve around environments leading to the removal of cellular water. Technically, these include any environment with a reduced water activity or a low water potential, including syrups, brines, and even some hypersaline lakes and salinas. While peripheral to the main treatment, the microorganisms occurring in these rather wet “dry” environments provide some insight into some of the mechanisms available to microorganisms living in the truly dry environments – dry soils and all aerial and subaerial environments, especially those in arid regions, the exterior of spacecraft, and dried grains and other foodstuffs – and so will not be explicitly excluded. The discussion will focus, however, on the microorganisms of arid regions, because they experience the widest range of extreme conditions, and, in consequence, display the broadest set of adaptations. Readers interested in a more thorough understanding of hypersaline environments should consult the Further Reading section.

Microbial Associations in Arid Regions

Traditionally, deserts have been defined as regions with barren landscapes and limited water, with the degree of water limitation usually defined on the basis of annual precipitation (see Office of Arid Land Studies, University of Arizona, 1968; Rainey et al., 1999). Thornwaite (1948) pointed out that a definition based strictly on precipitation is incomplete, in that it ignores the effects of temperature and plant cover on the fate of the precipitation. Instead, he championed a comparison of the actual annual precipitation with the potential evapotranspiration in the delineation of climatic regions. This approach was followed in the development of some of the first precise global maps of arid regions in the early 1950s (Meigs, 1953). Currently, arid regions sensu lato are defined as those parts of the world where the ratio of the mean annual precipitation (P) to the mean annual potential evapotranspiration (ETP) is less than 1. This definition emphasizes the water deficit of the region, which is greater for hotter deserts where the rate of evaporation is greater. Four intergrading zones have been delineated: the hyperarid zone with P/ETP less than 0.03; the arid zone with P/ETP between 0.03 and 0.20; the semiarid zone with P/ETP between 0.20 and 0.50; and the subhumid zone with P/ETP between 0.50 and 0.75 (see UNESCO, 1979; Parsons and Abrahams, 1994). In this system, regions previously classified as deserts on the basis of a mean annual precipitation of less than 200 mm per year correspond roughly to the hyperarid and arid climate zones. Together, these comprise in excess of 20% of the Earth's terrestrial surface. Semiarid regions, including steppes, savannahs, and similar habitats, cover another 16% (Walton, 1969). Such a large area encompasses a diversity of habitats and associations. In this article, we touch upon three broad clusters of associations: the soil microbiota, biological soil crusts, and rock-inhabiting microorganisms (Fig. 1; Table 1).

The Microbiota of Desert Soils

Numerous studies over the past several decades have indicated the presence of a remarkably diverse assemblage of microorganisms in soils from both hot and cold deserts (see Vishniac, 1993, 2002; Kieft, 2002; Cary et al., 2010). Included in most assemblages are a number of cosmopolitan species, which gives the overall assemblage an appearance similar to what would be expected from milder climates. This raises questions concerning (1) how harsh the desert soil climate is; (2) what role the cosmopolitan species play in the species assemblage; and (3) whether there exists a microbiota indigenous to desert regions. It is possible that a number of the bacteria isolated from desert soils are recent additions, carried in by wind, dust, or human activity, and not truly active members of the ecosystem. This is especially true for the cold McMurdo Dry Valleys region of Antarctica (also known in the literature as the Ross

Fig. 1 Diagrammatic representation of the major microbial associations in dry environments. (a) Biological soil crust. (b) Hypolithic associations. (c) An endolithic association.

Table 1 Characteristics of the more common habitats

Habitats/ associations	Ecological features
Edaphic habitats	On or in bare soils; surface fully exposed to the environment; exposure decreasing with depth; subject to disturbance (burial and erosion) from wind and flowing water, animal movement
Biological soil crusts	Fully exposed to the environment; insolation, desiccation, and wind erosion may be ameliorated by the structure of the association and the degree of connectivity with the underlying soil
<i>Lithic habitats</i>	
Epilithic	Fully exposed to the environment, organisms experience extremes of insolation, desiccation, long- and short-period temperature variation, wind erosion; generally restricted to relatively moist regions
Endolithic	With varying degrees of protection from environmental conditions: light filtered by the rock substratum; water retained by the physical structure of the substratum; wind erosion reduced by the overlying rock material; short-period temperature variations reduced, long-periods variations similar to those of the epilithic habitat; limited space for growth of the association
Chasmoendolithic	Protection from environmental conditions depending, in part, on the nature of the habitat – macroscopic cracks lead to more exposure to desiccation, but may be more efficient in collecting water and wind-blown nutrients; habitats with microscopic cracks similar to cryptoendolithic habitats
Cryptoendolithic	Generally more protected from environmental conditions than chasmoendolithic habitats because of the absence of a direct connection to the surface
Euendolithic	Restricted to the upper millimeter of the rock surface, therefore with a high degree of exposure to environmental conditions, especially insolation and desiccation
Hypolithic	Highest degree of protection from environmental conditions: light reduced by transmission through the overlying stone; long- and short-term temperature variations reduced; possible transport of moisture and nutrients to the habitat from the underlying soil
Perilithic	Subset of the hypolithic habitat relying on the condensation of water on the relatively large upper surface of the stone

Desert), where the conditions would tend to preserve nonindigenous cells in a nonmetabolic state for extended periods of time. Even with the possible inclusion of a number of nonindigenous forms, in hot deserts there does seem to be a skew in favor of desiccation-tolerant forms. This manifests itself in the proportionally larger numbers of spore-forming Gram-positive bacteria, especially spore-forming actinobacteria, and in the relative proportion of filamentous fungi (Fuller, 1974; Rainey et al., 1999; Kieft, 2002). There is a shift toward radiation-resistant forms in arid soils, especially members of the genus *Deinococcus*, with up to nine species present in a single soil sample (Rainey et al., 2005). Such a shift is consistent with the suggestion that radiation resistance in bacteria is actually a side effect of adaptations to water stress (Mattimore and Battista, 1996). In the interior of the cold McMurdo Dry Valleys region, in contrast, actinobacteria may only comprise about 3% of the cultured soil microbiota (Vishniac, 1993). The numbers of yeasts and filamentous fungi are also very low (Vishniac, 1996; Connell et al., 2006). *Deinococcus*, including several newly described species, however, is present (Hirsh et al., 2004). The low numbers of yeasts in McMurdo Dry Valleys soils are somewhat surprising in light of the fact that the dominant yeast in the region, *Cryptococcus vishniacii*, is considered to be both endemic- and desiccation-resistant (Vishniac, 2002).

Early studies of desert microorganisms relied on standard culture-based techniques. It is now recognized that many of the bacteria in environmental samples cannot be cultured on standard media, or, for that matter, on any media yet devised. Therefore, in recent years a number of molecular techniques have been developed, primarily based on direct or indirect analysis of gene sequences, but including fatty acid analysis and community-level physiological profiling (Torsvik et al., 1998; Kirk et al., 2004). Application of some of these techniques to desert soils has indicated the presence of a number of heterotrophic organisms not previously seen in culture-based studies, including members of the domain Archaea (Dunbar et al., 2000; Rutz and Kieft, 2004; Adams et al., 2006; Chanal et al., 2006; Smith et al., 2006; Lester et al., 2007; Yergeau et al., 2007; Niederberger et al., 2008). Even bacteriophage, either as prophage (viral genetic material incorporated into the bacterial genome) or as virus particles in bacteria in a pseudolysogenic state (infecting the cell, but maintained separately from the genome), but not as free particles, have been detected in the subsurface desert sands (Prigent et al., 2005), and in Antarctic soils and lithic environments (Zablocki et al., 2014). The full significance of these results is yet to be elucidated. At a minimum they suggest that the diversity of desert soil bacteria is much greater than was previously realized (Niederberger et al., 2008; Cary et al., 2010).

Traditionally, the phototrophic assemblage in desert soils has been evaluated using direct microscopic observation of field samples supplemented with cultures derived from the samples (see, e.g., Friedmann et al., 1967). Based on these types of studies a picture arose of deserts populated by a relatively simple assemblage dominated by coccoid green algae (*Chlorococcum*, *Chlorella*, *Stichococcus* and others) and filamentous cyanobacteria (*Lyngbya*, *Schizothrix*, *Microcoleus*, *Scytonema*, *Nostoc* and others), with coccoid cyanobacteria and other groups of eukaryotic algae present in smaller numbers (Friedmann and Galun, 1974). As was recognized early on, the simple and variable morphology of many of the desert phototrophs makes identification from field material difficult, while culture techniques tend to favor cosmopolitan generalists instead of the ecological specialized, and perhaps more significant, members of the association (Friedmann et al., 1967); this is the same problem encountered in culture-based studies of heterotrophic bacteria. Improved culture methods and the application of molecular techniques are beginning to provide us with better understanding of the true diversity of the desert phototrophic assemblage (Cardon et al., 2008; Osorio-Santos et al., 2014; Patzelt et al., 2014; Pietrasiak et al., 2014; Fig. 2).

As expected, the numbers of soil bacteria in deserts tend to be lower than in comparable soils from more temperate climates. Reported plate counts from a variety of hot desert soils range from a low of less than 10 cfu g^{-1} to $1.6 \times 10^7\text{ cfu g}^{-1}$, numbers at least 2 orders of magnitude lower than is typical for agricultural or forest soils (Kieft, 2002). The lowest recorded numbers are from the vicinity of Yungay in the hyperarid core of the Atacama Desert, Chile (Navarro-González et al., 2003). This region has generated considerable interest among microbiologists and astrobiologists because it is considered to be one of the oldest and most extreme of the hot deserts, and can be considered a terrestrial analogue of Mars (McKay et al., 2003). Some microbiologists, because of the low numbers of bacteria recovered, suggest that the dry conditions in the hyperarid core of the Atacama may be near the boundary for life in desert environments (Navarro-González et al., 2003). Others dispute this view on the basis of their own higher counts; they suggest that the boundary for life has yet to be found on Earth (Drees et al., 2006; Lester et al., 2007). No matter which group is right, it is clear that large-scale shifts in the moisture regime have a significant impact on the total number of desert soil bacteria.

The cold deserts of Antarctica have also been cited as being at or beyond the limits of life; there are several examples of studies where the number of colony-forming units (cfu) in soil from the McMurdo Dry Valleys region of the Antarctica was below detectable limits (Horowitz et al., 1972). However, the apparent sterility of at least some of the samples may have been an artifact of the medium used (standard nutrient agar); true oligotrophs and some nutrient-starved bacteria are unable to grow on this relatively rich medium. Later sampling of similar soils using oligotrophic media containing 0.1% peptone and 0.02% yeast extract enriched with soil extracts from the site yielded significantly higher numbers of bacteria, suggesting that viable cells can be presumed to be present in all soils not containing toxic substances (Parker et al., 1982; Vishniac, 1993, 2002). The absolute number and diversity of soil bacteria varies widely, depending on the type (e.g., ornithogenic, enriched with bird wastes vs. mineral, with limited organic material), the local climate, and the technique used (Vishniac, 1993; Aislabie et al., 2006; Yergeau et al., 2007;

Niederberger et al., 2008; Lee et al., 2012). Away from the coast, the numbers are similar to those encountered in the Atacama Desert, on the order of 10^3 – 10^5 cfu g⁻¹ soil, when procedures similar to those used in the Atacama studies, plate counts on R2A agar, a low-nutrient medium designed to count slow-growing heterotrophic bacteria in stressed environments, are used. The more arid Antarctic soils generally harbor relatively small numbers of cyanobacteria and microalgae (Aislabie et al., 2006; Wood et al., 2008; Pointing et al., 2009; Khan et al., 2011).

The source of the organic carbon supporting the low numbers of heterotrophic bacteria in the Antarctic Dry Valleys, and other extreme deserts, is not completely clear. In the milder deserts, shrubs and animal mounds provide obvious sources of carbon and other nutrients, creating “islands of fertility” with bacterial populations up to two orders of magnitude larger than those found just a few decimeters away (Herman et al., 1995; Schlesinger et al., 1996; Kieft, 2002; Schade and Hobbie, 2005). These sources of nutrients are completely lacking in the more extreme deserts. Therefore, the heterotrophic microbial community must rely on in situ production by cyanobacteria and microalgae, importation of carbon from more productive regions, or relic carbon remaining in the soils from periods when the climate was more benign (Fountain et al., 1999; Virginia and Wall, 1999; Burkins et al., 2000, 2001; Elberling et al., 2006; Hopkins et al., 2006; Cary et al., 2010). There is evidence suggesting that, at least for the lower elevations of Taylor Valley, Antarctica, relic organics deposited either as entrained material in glacial tills or as primary production in ancient glacial lakes are the primary source of organic material in the soil and that this legacy material may sustain the microbial soil community in the absence of any other inputs to the system (Burkins et al., 2000). However, field measurements of short-term respiration rates, coupled with known meteorological parameters, indicate a carbon release rate of 6.5 g C m⁻² year⁻¹; at this rate the mean residence time for carbon would be 23 years, not the thousands of years expected (Burkins et al., 2001). This suggests the presence of significant in situ production since the carbon signature of the organic material rules out inputs from the surrounding habitats. The legacy carbon may exist in a recalcitrant form unavailable to the community under normal conditions (Burkins et al., 2001; Barrett et al., 2006; Hopkins et al., 2006). This two-compartment model of soil carbon, one compartment labile, one compartment recalcitrant, may prove to be of value in the analysis of other desert systems.

Biological Soil Crusts

Biological soil crusts are created by surface-bound assemblages of microorganisms that consolidate the soil into crusts up to a centimeter thick (Garcia-Pichel, 2002; Fig. 3). Much of our current knowledge of this system has been summarized previously; those wishing a thorough review are directed to the Further Reading section (Belnap and Lange, 2003). Here we will just touch upon a few highlights.

Biological soil crusts are widespread, occurring on all of the continents and in most biomes, essentially wherever a shortage of water limits the growth of vascular plants, thereby allowing light to reach bare soil, but there is still sufficient water to allow the growth of phototrophic microorganisms (Garcia-Pichel, 2002; Büdel, 2003c; Belnap and Lange, 2003; Pócs, 2009). They reach their greatest development in semiarid and arid environments, where they can cover more than 90% of the ground surface (Johansen et al., 2001; Belnap et al., 2003; Thomas and Dougill, 2007; Zaady et al., 2007; Zhang et al., 2007). In such cases biological soil crusts may provide a significant fraction of the photosynthetically fixed carbon (Lange, 2003; Evans and Lange, 2003; Burgheimer et al., 2006; Thomas and Dougill, 2007; Pointing and Belnap, 2012), serve as sources of fixed nitrogen (Belnap, 2003a; Evans and Lange, 2003; Bhatnagar and Bhatnagar, 2005; Pointing and Belnap, 2012), reduce soil erosion (Belnap, 2003b; Eldridge, 2003; Warren, 2003a,b; Williams et al., 2012), and influence local and regional hydrologic cycles (Warren, 2003a,b; Eldridge, 2003; Yair, 2003; Belnap, 2006; Thomas and Dougill, 2007; Williams et al., 2012). Extensive growths of biological crusts can be mapped using aerial photography and satellite-based imagery (Karnieli et al., 2003; Zhang et al., 2007; see also Warren-Rhodes et al., 2007a,b,c).

The distribution, composition, and appearance of biological soil crusts depend primarily on moisture and climatic conditions, secondarily on soil properties (Johansen et al., 2001; Belnap et al., 2003; Büdel, 2003c; Ullmann and Büdel, 2003b; Bowker et al., 2006). On a broad scale, four distinct types of crusts can be recognized macroscopically (Belnap, 2003c, 2006). Smooth crusts, as

Fig. 3 Biological soil crusts in the Mojave Desert. (a) The desert landscape. Soil crusts appear as darker areas of the soil surface. (b) A closer view of the crust. In this instance the crust form a pattern of darker bands. The total length of the scale bar in the foreground is 10 cm.

suggested by the name, are recognized by the smoother appearance of the soil surface resulting from activity of cyanobacteria, algae, and fungi. The biological components spend much of the time just below the surface, only appearing when the soil is wet. This type of crust is most prevalent in hyperarid and arid regions with very low precipitation and very high temperatures (Belnap, 2003c). Rugose crusts, which give the soil surface a rough appearance, are common in arid regions with a slightly moister climate. They are also dominated by cyanobacteria, green algae, and fungi, but may include varying numbers of lichens and desiccation-resistant mosses (Belnap, 2003c). Pinnaced crusts are characterized by the presence of a patchwork of mounds up to 15 cm in height but only a few millimeters in width, caused by a combination of frost heaving during the winter and differential erosion during the rest of the year. Cyanobacteria are the dominant microorganisms, but lichens and mosses may contribute up to 40% of the cover. Pinnaced crusts are found in some of the cooler deserts, where freezing temperatures are possible (Belnap, 2003c). Rolling crusts are also associated with frost heaving. However, in this case, a thicker growth of mosses, lichens, and/or cyanobacteria reduces the amount of erosion, leading to a generally smoother appearance than that of the pinnaced crusts. Rolling crusts are characteristic of colder climates with a lower potential evaporation rate (Belnap, 2003c). Within these groupings, there is a tendency for sandy soils of low nutritional content to be dominated by cyanobacteria, with the proportion of lichens increasing with the carbonate, gypsum, and silt content of the soil (Büdel, 2003c; Ullmann and Büdel, 2003b).

From the limited data available, it appears that the abundance of soil crusts decreases as the climate becomes more arid. For example, in Central Asia, biological crusts are described as abundant in the eastern semideserts of Mongolia, present in the central Gobi Desert (Büdel, 2003a), and covering about 29% of the land in the relatively drier Gurbantunggut Desert farther west (Zhang et al., 2007). Within the Gurbantunggut Desert there is a marked decrease in the abundance of crusts in the northern regions of the desert, which corresponds to a decrease in the amount of precipitation (Zhang et al., 2007). Similarly, in southern Africa, the development of biological soil crusts appears to be linked to the frequency of rains and the duration of the dry periods (Büdel et al., 2009). The development of crusts in the Sahara Desert may be restricted by climate and surface instability to the marginal regions (Ullmann and Büdel, 2003a). However, there has only been a single study of soil crusts from the region (Ullmann and Büdel, 2003a). True soil crusts are rare in the Atacama Desert, usually restricted to moister sites in the south (Patzelt et al., 2014) and coastal regions near the port cities of Antofagasta and Caldera (Büdel, 2003b); *Nostoc* crusts are present in southern Peru (Rauh, 1985). In the drier parts of Antarctica, away from the coasts, small patches of cyanobacterial crusts occur sporadically in widely scattered locations (Green and Broady, 2003).

Common microbial constituents of biological soil crusts include members of the filamentous cyanobacterial genera *Microcoleus*, *Nostoc*, and *Scytonema* (Friedmann and Galun, 1974; Dor and Danin, 2001; Belnap et al., 2003; Büdel, 2003c). Filaments of *Microcoleus* are formed from numerous trichomes within a common sheath. The individual trichomes are motile within the sheath and may even, when conditions warrant, leave the sheath. In the latter case, trichomes will group and secrete a new sheath later. The buildup of used and new sheath material contributes to the stability of the soil crust (Dor and Danin, 2001; Belnap et al., 2003; Pointing and Belnap, 2012). Members of *Nostoc*, especially *Nostoc commune*, frequently form large masses of coiled trichomes within a communal polysaccharide sheath. Masses of *N. commune* can become large enough to harvest and are apparently used as a supplemental food source for humans in some regions (Belnap et al., 2003). Heterocysts, specialized nitrogen-fixing cells, are common within the colonies. Filaments of *Scytonema* are formed from a single trichome with heterocysts and false branching within a colored sheath. Trichomes reproduce through the formation of small motile filaments called hormogonia. Additional common phototrophic microorganisms include the cyanobacterium *Gloeocapsa* and members of the green algal genera *Chlorococcum*, *Macrochloris*, and *Stichococcus* (Belnap et al., 2003). It should be kept in mind, however, that the actual diversity of photosynthetic microorganisms in the desert crusts is much greater than indicated here. Molecular analysis of isolates and natural samples from North America (Garcia-Pichel et al., 2001; Lewis and Flechtner, 2002; Lewis and Lewis, 2005) suggests that biological soil crusts can almost be considered biodiversity hot spots. Somewhat surprisingly, soil crust fungi and heterotrophic bacteria have so far been virtually ignored (States et al., 2003).

Rock-Inhabiting Microorganisms

Most deserts contain extensive regions covered by rock outcrops or by bare soils with embedded or loose-lying cobbles, pebbles, and stones. The importance of rock, or lithic, habitats in these regions is suggested by the variety of terms derived from indigenous languages used to describe them. In the Middle East and northern Africa, regions characterized by rock outcrops, large boulders, and limited soil are called hamadas. Regions characterized by smaller stones and pebbles accompanied by sandy or gravelly soil are referred to variously as reg (western Sahara, the Iranian desert), serir (the Libyan and Egyptian Sahara), gobi (Mongolia), or gibber plains (Australia). Desert pavement is used specifically for those parts of the desert covered by embedded stones in a relatively compact arrangement (Dixon, 1994).

Lithic habitats can be divided into three distinct habitats corresponding loosely to the extremes of environmental conditions encountered by the microbial inhabitants. The *epilithic* habitat corresponds to the upper surface of the rock or stone, the part most directly exposed to atmospheric and climatic conditions and, therefore, more directly exposed to environmental extremes. The *endolithic* habitat corresponds to the interior of the rock or stone. Three distinct subdivisions of this habitat can be identified (Golubic et al., 1981): the *cryptoendolithic* habitat, consisting of naturally occurring pore spaces within the rock; the *chasmoendolithic* habitat, consisting of cracks and fissures in the rock leading to the surface; and the *euendolithic* habitat, consisting of holes and pits created by the metabolic activity of the microbial community (Fig. 4). The *hypolithic* habitat consists of the lower surface of a stone in association with adherent soil particles (The term "sublithic" is sometimes used, erroneously, as a synonym for hypolithic.).

Fig. 4 Diagrammatic representations of endolithic habitats and associations. (a) Euendoliths, boring into the rock either individually (left) or as part of a lichen association (right). (b) A cryptoendolithic association. (c) A chasmoendolithic association inhabiting microfractures in a weathered substratum. The drawings are not to scale. However, scale bars have been included to provide an indication of the relative dimensions of the habitat – in figure (a) the bar represents 1 mm, in figures (b) and (c) it represents 1 cm.

Recently, the term perolithic has been introduced to distinguish the subsurface sides of large stones from the true hypolithic habitat below the stone (Warren-Rhodes et al., 2007a,b,c). The hypolithic and perolithic habitats are similar, but differ slightly in their moisture and light regimes.

Epilithic Associations

In relatively moist regions epilithic cyanobacteria and cyanophilous lichens form extensive growths, capable of completely covering the surface of large inselbergs, rock hills arising abruptly from the surrounding plains (Büdel, 1999). In hot arid regions, such growths are essentially absent (Büdel, 1991). Instead, the dominant epilithic microbial community is that associated with rock varnishes. Rock varnishes are thin, dark layered veneers of clay minerals held together by oxides and hydroxides of manganese and iron (Kuhlman et al., 2006). They are found in all weathering environments, but are most common in arid lands, where they are referred to as desert varnishes. There is a long-standing debate concerning the origins of rock varnishes with some advocating the predominance of physical–chemical mechanisms and others advocating biological mechanisms (see Nagy et al., 1991; Krinsley, 1998; Perry and Kolb, 2004; Perry et al., 2006 for brief reviews). It is also possible that the mechanism may change with changing climatic conditions (Liu and Dorn, 1996). Resolving this debate is beyond the scope of the present article. Our interest is in the

presence of a ubiquitous and relatively diverse microbial community in what is considered to be a dry environment (Kuhlman et al., 2006). Included are actinobacteria, *Bacillus*, *Micrococcus*, *Metallogenium*-like strains, cyanobacteria, and microcolonial fungi (see Krumbein and Jens, 1981; Kuhlman et al., 2006). Nearly all of the heterotrophic strains of bacteria isolated are Gram-positive and are capable of precipitating manganese. Populations of bacteria in rock varnishes from the eastern border of the Mojave Desert are on the order of 10^7 – 10^8 cells per gram of varnish, estimated on the basis of direct microscopic observation and phospholipid fatty acid analysis (Kuhlman et al., 2006), somewhat remarkable given their exposed position. Raman spectroscopy of varnishes from Colorado and Nevada indicates the presence of chlorophyll, scytonemin, and β -carotene (Edwards et al., 2004); the latter two are considered to be bioprotective molecules (see below).

Endolithic Associations

Euendolithic associations

Euendolithic microorganisms, which use chemical reactions to bore into the surfaces of rocks, are common in aquatic systems (see, e.g., Pentecost and Whitton, 2000; Priess et al., 2000; Radke and Golubic, 2005; McLoughlin et al., 2007), less so in terrestrial systems (Fig. 4). The decrease in abundance in terrestrial systems is caused, presumably, by the need for suitable substrates, generally carbonates although volcanic glasses are possible (McLoughlin et al., 2007), and for sufficient external moisture to support the chemical reaction. In fact, moisture is more of a problem in euendolithic systems than in other terrestrial endolithic systems because there is a direct connection between the colony and the external environment. One way around the moisture problem is the formation of a lichen association – the added mass and the structure of the lichen thallus could serve to maintain a moist environment long enough for both significant metabolic activity and the dissolution of the rock material to take place. In fact, euendolithic lichens are widespread, at least in Europe and the eastern Mediterranean, on calcareous rocks in microclimates where air humidity is high and light intensity is low (Tretiach and Pecchari, 1995; Tretiach and Geletti, 1997). Their activity may contribute significantly to the deterioration of marble buildings and monuments (Danin and Caneva, 1990).

Extensive growths of euendolithic lichens have even been reported from the moister regions of the Negev Desert (Danin et al., 1982; Danin and Garty, 1983; Danin, 1986; Garty, 1999). Here, the distribution is linked to the local microclimate through the imbibition time, an indicator of how many hours a year a lichen thallus is moist. If the conditions result in more than 450 h of daylight imbibition time epilithic lichens dominate, between 300 and 450 h of imbibition euendolithic lichens dominate, and at lower levels the free-living euendolithic fungus *Lichenothelia* dominate in loose association with cryptoendolithic and chasmoendolithic cyanobacteria and eukaryotic algae (Danin and Garty, 1983). Because the different associations form distinctive patterns on the surface of the rock, which can persist long after the association has disappeared, they can be used as indicators of the climate at the time the community was destroyed by fire or burial (Danin et al., 1982; Danin, 1986). The small pits and other scars in the rock surface may also facilitate the recolonization of the surface by desert microorganisms (Garty, 1992).

Free-living colonies of euendolithic coccoid cyanobacteria have also been reported from several locations in Israel. If true, these would represent the first such reports from a terrestrial setting (Danin and Garty, 1983; Danin et al., 1983; Danin, 1986). However, it is possible that the colonies were actually lichenized, but with a small proportion of fungi (Nienow et al., 2002). More recently a species of the filamentous heterocystous cyanobacterial genus *Matteia* has been isolated from Negev limestones. This species is capable of boring into limestone rocks both in culture and in the Negev, thus demonstrating unequivocally the existence of free-living terrestrial euendoliths (Friedmann et al., 1993a,b).

Outside of the Negev, there are almost no reports of euendolithic associations of any sort from arid regions. The euendolithic lichen *Verrucaria calciseda* is described as widely scattered in temperate and boreal regions rich in limestones, including northern Arizona (Brodo et al., 2001). The euendolithic lichen *Verrucaria rubrocincta* is present in caliche deposits in the Sonoran Desert (Bungartz et al., 2001). Filamentous and coccoid cyanobacteria coat the insides of small (0.1–0.5 mm) pits, presumably made by the action of the cyanobacteria, in the surface of limestone pinnacles in Western Australia (Pócs, 2009).

Chasmoendolithic associations

Like euendolithic systems, chasmoendolithic systems have a direct connection with the surface, allowing light, moisture, and nutrients to reach the association relatively unimpeded. As a result, a wide variety of rock types, including darker basalts and granites, can sustain chasmoendolithic growth at some depth. In spite of their widespread occurrence in a variety of climate zones, including desert regions, there have been relatively few detailed investigations of either the habitat or the organisms within (Friedmann and Galun, 1974; Garty, 1999; Nienow et al., 2002). The most extensive studies are from the relatively mild Vestfold Hills and Mawson Rock regions of Antarctica and from the hyper-arid portions of the Atacama Desert in Chile. In the Antarctic, the chasmoendolithic association contains a diverse group of microalgae, with members of cyanobacterial genera *Chroococcidiopsis* and *Plectonema* and the green algal genera *Desmococcus* and *Prasiococcus* the most widespread in the habitat. These can be grouped into associations dominated by *Desmococcus*, common in the drier regions, or by *Chroococcidiopsis*, common in the wetter regions of the Mawson Rock site (Broady, 1981a). The domination of *Chroococcidiopsis* in the wetter and not the drier sites was unexpected given the frequency of reports of *Chroococcidiopsis* from arid deserts. A few of the associations displayed a distinct zonation pattern, with either *Prasiococcus* or *Desmococcus* forming an outer green band and *Chroococcidiopsis* forming an inner bluish-green band. At the Vestfold Hills site, extensive development of chasmoendolithic associations is restricted to the slopes of hills and boulders sheltered from the wind (Broady, 1981a).

Chasmolithic lichen associations and cyanobacterial biofilms from the Granite Harbor region of Antarctica have been shown to develop acidic microenvironments within the association that may be involved in weathering of the substratum (de los Rios et al., 2003) – chasmoendolithic associations are often implicated in the weathering of marble and limestone monuments in the semiarid Mediterranean region (Garty, 1999). Molecular analysis indicated the presence of what may be a relative of the chlorophyll d-containing cyanobacterium *Acaryochloris marina* in the association; this is the first record of this group of cyanobacteria in a terrestrial endolithic environment (de los Rios et al., 2007).

As might be expected, the chasmoendolithic association in the drier Atacama Desert is less diverse, with no eukaryotic phototrophs detected either visually (microscopically) or through molecular methods (DiRuggiero et al., 2013). Instead, the system is dominated by members of the genus *Chroococcidiopsis*, with the presence of small numbers of filamentous cyanobacteria and heterotrophic bacteria indicated by molecular techniques (DiRuggiero et al., 2013).

Cryptoendolithic associations

Cryptoendolithic organisms inhabit the interstitial spaces of porous rocks. Because the organisms lie below the surface of the rock, without a direct light path to the surface, only rocks composed of light-colored or translucent grains are colonized by cryptoendolithic phototrophs. Cryptoendolithic associations are easily recognized macroscopically as a pigmented layer running more or less parallel to the surface of the rock at a depth of one to a few millimeters. They can develop in any environment, wherever suitable rocks are exposed to sufficient light (van Thielen and Garbary, 1999; Nienow et al., 2002). Examples have been reported from weathered granites, gneisses, limestones, and marbles, including some used as building materials (see Nienow and Friedmann, 1993; van Thielen and Garbary, 1999; Nienow et al., 2002; Wong et al., 2010 and the references therein), beachrock (Krumbein, 1979; Schreiber et al., 2002), gypsum crusts (Hughes and Lawley, 2003; Boison et al., 2004; Dong et al., 2007; Wierzbos et al., 2010), halites and evaporites (Rothschild et al., 1994; Wierzbos et al., 2006), sinters associated with geothermal environments (Walker et al., 2005; Phoenix et al., 2006), dark volcanic basalts (Jorge Villar et al., 2006), and gneisses altered by asteroid or comet impacts (Cockell et al., 2002). However, the most commonly colonized substrata appear to be porous quartz sandstones (Friedmann and Ocampo-Friedmann, 1984; Bell, 1993; Nienow et al., 2002; Omelon et al., 2006; Pócs, 2009; Fig. 5).

Fig. 5 Examples of endolithic associations. (a) Cryptoendoliths inhabiting a sandstone in the dry valley region of Antarctica. In this instance the association causes a characteristic weathering pattern visible on the surface of the rock that leads to flaking of the crust surface (seen in the center of the image). The association is visible to the right of the image, where the rock has been broken off. (b) An endolithic association from the Mojave Desert. (c) An endolithic association inhabiting halite in the Atacama Desert. The scale bars in figures b and c represent 1 cm.

The most extensively studied cryptoendolithic associations from desert regions are those found in porous sandstones in the McMurdo Dry Valleys regions of Antarctica (Nienow and Friedmann, 1993; Nienow et al., 2002; Sun et al., 2010). One of the most striking features of these associations is the complexity of the system. At least five distinct associations, three of which are widespread, have been described. The most abundant is generally referred to as the lichen-dominated community or the cryptoendolithic lichen community. It can be recognized macroscopically by the presence of parallel black, white, and green bands a few millimeters below the rock surface. The black layer consists of dark-pigmented filamentous fungi and lichenized cells of the green algal genus *Trebouxia* (or, possibly, *Pseudotreboxia*). The white layer is populated by green algae and hyaline filamentous fungi, possibly a morphological variant of some of the black fungi from the upper layer; it appears white because the iron oxides that normally give the rocks their characteristic brown to orange-red color have been leached from this layer (Nienow and Friedmann, 1993; Nienow et al., 2002). Included among the dark-pigmented fungi are a number of nonlichenized meristematic black fungi, typically members of *Friedmanniomyces* and *Cryomyces* in the Dothideomycetidae, a taxonomic order known to have many stress-tolerant members (Onofri et al., 1999; Selbmann et al., 2005). A number of culture-based and molecular studies indicate the presence of a small but diverse heterotrophic bacterial community dominated by actinobacteria, but including members of *Deinococcus* (Nienow et al., 2002; de la Torre et al., 2003).

The *Hemichloris* community can be recognized as a green band several millimeters below the surface of the rock. Typically, it develops below the white layer of the lichen-dominated community, but can also be found as the sole community inhabiting the lower surface of overhanging sandstone ledges (Nienow et al., 1988, 2002). The community is named after its dominant member, the green alga *Hemichloris antarctica* (Tschermak-Woess and Friedmann, 1984). Included in the community is a diverse assemblage of cyanobacteria and eukaryotic algae, including a second species of *Hemichloris* (Tschermak-Woess et al., 2006), the endemic species *Heterococcus endolithicus* (Darling et al., 1987), and members of the green algal genus *Stichococcus* and the cyanobacterial genera *Gloeocapsa* and *Chroococcidiopsis*. Members of *Stichococcus*, *Gloeocapsa*, and *Chroococcidiopsis* are all common constituents of terrestrial systems; *Stichococcus bacillaris* is generally considered to be a cosmopolitan inhabitant of subaerial environments, including lithic environments in Antarctica (Nienow and Friedmann, 1993; Broady, 1996; Hughes, 2006). The species of *Chroococcidiopsis* in this community is similar to that described in other endolithic and hypolithic communities.

The *Hormathonema*–*Gloeocapsa* community is a complex cyanobacteria-dominated community only found on Battleship Promontory, where it colonizes white sandstone boulders permanently wetted by snowmelt percolating through the dolerite rubble at the base of the rocks; the drier upper surfaces of large outcrops in the region are colonized by the lichen-dominated community. It can be recognized macroscopically by the presence of two parallel color bands below the rock surface, without a leached zone in between. The upper layer is a complex assemblage of cyanobacteria dominated by members of the genera *Hormathonema* and/or a dark gray species of *Gloeocapsa*. The lower green band is dominated by a species of *Aphanocapsa*, occasionally accompanied by several species of *Gloeocapsa*, *Anabaena*, and *Lyngbya* (Friedmann et al., 1988). The heterotrophic component of the community includes flagellated protozoans, filamentous fungi, and yeasts and up to 39 morphotypes of heterotrophic bacteria (Hirsch et al., 1988). Molecular analysis indicates the presence, among others, of actinobacteria and members of the *Thermus*–*Deinococcus* group (de la Torre et al., 2003).

The remaining associations are referred to as the *Chroococcidiopsis* community and the red *Gloeocapsa* community (Friedmann et al., 1988). Both are dominated by unicellular cyanobacteria of similar morphology. The *Chroococcidiopsis* community was the first endolithic community discovered in Antarctica (Friedmann and Ocampo, 1976 (*Chroococcidiopsis* is referred to as *Gloeocapsa* in this paper)). It appears as a single green or brownish band just below the surface crust, and *Chroococcidiopsis* sp. is the sole phototrophic organism. When discovered, it seemed to confirm a pattern just then beginning to be recognized: in the most extreme deserts where environmental conditions preclude eukaryotes and filamentous cyanobacteria, the unicellular *Chroococcidiopsis* becomes the dominant or sole photoautotroph (Friedmann and Galun, 1974 (again *Chroococcidiopsis* is referred to as a probable member of the genus *Gloeocapsa*), Friedmann and Ocampo-Friedmann, 1995). The relatively limited distribution of the *Chroococcidiopsis*-dominated community in the Antarctic desert suggests that this polar desert may not be the most extreme on Earth, although it remains the closest terrestrial analogue to Mars.

It has been estimated that cryptoendolithic associations colonize 20–30% of the exposed surfaces of Beacon sandstones in the McMurdo Dry Valleys region, equivalent to a total colonized area of between 200 and 300 km² (Friedmann et al., 1993a,b). Given the abundance of material in an association, 1.4–7.4 g N (Kjeldahl)m⁻², or 35–190 g C m⁻² (Friedmann et al., 1980; Sun and Friedmann, 1999), this represents a significant pool of organic matter in a desert region and suggests that endolithic organisms play an important role in the ecosystem. How significant is a matter of debate. Short-term laboratory measurements of CO₂ gas exchange under different temperature conditions coupled with multiyear records of environmental conditions with colonized surfaces suggest net and gross primary productivity rates on the order of 600 and 1200 mg C m⁻² year⁻¹, respectively (Friedmann et al., 1993a,b). At this rate of incorporation, a fully developed community could replace itself within 300 years. Multiple lines of evidence suggest that the endolithic communities grow much more slowly than this. Radiocarbon dating of endolithic communities (McKay et al., 1986; Bonani et al., 1988), carbon turnover times (Johnston and Vestal, 1991), comparisons of the rates of biogenic and abiogenic weathering (Friedmann and Weed, 1987; Sun and Friedmann, 1999), and estimates of the number of metabolically active hours per year (Friedmann et al., 1987; McKay et al., 1993) and the number of divisions per year in the lower levels of the community (Nienow et al., 1988) all indicate that the age of a well-developed community is on the order of 1000–10,000 years. Some of the material, especially low-molecular-weight compounds lost during rewetting, may be leached from the community, ending up, eventually, in the surrounding soils (Friedmann et al., 1993a,b). It is not clear how significant this leaching is. Dr. H. Sun (Desert Research Institute, Las Vegas, personal communication) found that most of the free amino acids were concentrated in the

upper few centimeters of the lichen-dominated community. Chemical signatures indicative of the cryptoendolithic community are present in soils from the higher elevations in Taylor Valley, but not in soils from the lower elevations (Burkins et al., 2000).

Cryptoendolithic associations are widespread outside of Antarctica, although not nearly as intensely investigated (Nienow et al., 2002). In most cases, they occur in some sort of sandstone substratum. Here, they take on the same macroscopic appearance. There is a colored band beginning just below the surface of the rock, extending inward just a few millimeters at most (Friedmann and Galun, 1974; Bell, 1993). The composition of the community depends, at least to a degree, on the aridity of the environment. For example, in the vicinity of the Colorado Plateau in North America, the relative abundance of eukaryotic green algae increases in comparison with cyanobacteria in the milder upper elevations – at the milder sites, members of the green algal orders Chlorococcales and Chlorosarcinales comprise 50–75% of the phototrophic associations, while at the lower, more xeric sites, nearly 100% of the phototrophs are cyanobacteria (Bell et al., 1988). Generally speaking, however, most cryptoendolithic associations in hot deserts are dominated by members of the cyanobacterial genus *Chroococcidiopsis* (Friedmann and Galun, 1974; Bell, 1993; Nienow et al., 2002); in many cases *Chroococcidiopsis* appears to be the sole phototrophic taxon present (Friedmann and Galun, 1974; Bell, 1993; Nienow et al., 2002). The reduced importance of eukaryotic algae in hot desert endolithic associations is usually ascribed to temperature, rather than moisture concerns, although this has not been tested in detail; in fact, there are few data concerning the temperature ranges of hot desert forms.

Endolithic associations have also been reported from gypsum rocks in Antarctica, and in the hot Atacama, Jordanian, and Mojave deserts (Hughes and Lawley, 2003; Dong et al., 2007; Wierzbos et al., 2010). Preliminary investigations of the Antarctic community indicated the presence of a member of the cyanobacterial genus *Chloroglea* as the principal phototrophic member, with the fungal genus *Verticillium* and the bacterial genus *Sphingomonas* also represented (Hughes and Lawley, 2003). Overall, the biodiversity appears to be low (Hughes and Lawley, 2003). The hot desert gypsums contained a much more diverse assemblage (Dong et al., 2007; Wierzbos et al., 2010). The dominant phototrophs in most cases were morphologically similar to *Chroococcidiopsis*, with a small number of filamentous cyanobacteria in samples from the Mojave Desert (Dong et al., 2007). Somewhat surprisingly, Wierzbos and his colleagues found calcium sulfate crusts from the drier regions of the Atacama Desert were dominated by lichenized eukaryotic algae (Wierzbos et al., 2010); they attribute the dominance of eukaryotes to the lack of liquid water and the reliance of the association on water vapor.

A unique endolithic community exists in halite evaporites of nonmarine origin in the hyperarid core of the Atacama Desert (Wierzbos et al., 2006). The evaporites form extensive nodular crusts at several sites in the Atacama, including Yungay, Salar de Llamara, and Salar Grande (Pueyo et al., 2001; Wierzbos et al., 2006). The community forms a macroscopically visible grayish layer beginning a few millimeters below the surface and extending another 2–5 mm into the rock (Wierzbos et al., 2006). The dominant phototrophic organism in the community is morphologically similar to *Chroococcidiopsis* with a brown sheath (Wierzbos et al., 2006); phylogenetic analysis, however, indicates that the dominant phototroph in the system is more closely related to *Halotheca*, a cyanobacterium known from hypersaline environments (de los Ríos et al., 2010; Robinson et al., 2015). Heterotrophic bacteria and archaea are also present (Wierzbos et al., 2006; de los Ríos et al., 2010; Robinson et al., 2015).

Hypolithic Associations

Scientific study of hypolithic associations began with the pioneering work of Vogel (1955) in South Africa and Cameron and Blank (1966) in the American Southwest. Since then there have been additional reports from the Namib Desert in southern Africa (Rumrich et al., 1989; Büdel and Wessels, 1991; Warren-Rhodes et al., 2013); the Negev Desert in the Middle East (Friedmann et al., 1967; Friedmann and Galun, 1974; Berner and Evenari, 1978); the southwestern United States (Friedmann and Galun, 1974; Büdel and Wessels, 1991; Schlesinger et al., 2003); Australia (Tchan and Beadle, 1955; Tracy et al., 2010); the Atacama Desert in South America (Warren-Rhodes et al., 2006, 2007a,b,c); the arid northwestern region of China (Pointing et al., 2007; Warren-Rhodes et al., 2007a,b,c); the Dry Valleys region of Antarctica (Broadly, 1981b; Nienow and Friedmann, 1993; Broadly, 1996; Smith et al., 2000; Cockell and Stokes, 2006; Cowan et al., 2011; Khan et al., 2011); and the high Arctic (Cockell and Stokes, 2004, 2006). In most cases, colonized stones are composed of quartz, flint, or some other translucent material. These allow small but measurable amounts of photosynthetically active radiation to reach the phototrophic portion of the association, estimated to be on the order of 0.01–0.1% of the incident light at the lowest colonized levels (Vogel, 1955; Berner and Evenari, 1978; Schlesinger et al., 2003; see also Tracy et al., 2010; Cowan et al., 2011; Warren-Rhodes et al., 2013); similar numbers have been obtained for cryptoendolithic associations (Nienow et al., 1988; Matthes et al., 2001; Cockell et al., 2002). In one case, colonized dolomites from the Arctic, no light transmission was detected through 1-mm-thick sections of the substratum, suggesting that light reaches the community through the surrounding coarse-grained soil (Cockell and Stokes, 2006).

Phototrophic hypolithic associations form macroscopically visible green to bluish-green films on the lower surfaces of colonized stones (Fig. 6). In most of the instances, the reported community contains a remarkably diverse assemblage of species including a mixture of unicellular and filamentous cyanobacteria, green algae, and, in some cases, diatoms. For example, more than 23 species of hypolithic phototrophs have been recorded from Antarctica on the basis of light microscopy, including representatives of eight genera of cyanobacteria, three genera of green algae, two genera of yellow-green algae, and two species of diatoms (Broadly, 1981b, 1996). In the Namib Desert, representatives of over 50 species of just diatoms have been reported from hypolithic associations (Rumrich et al., 1989). More recent investigations using molecular techniques have confirmed this diversity in Antarctic associations (Smith et al., 2000; Pointing et al., 2009; Khan et al., 2011). The hypolithic association in a semi-arid region of northern Australia

Fig. 6 Examples of hypolithic associations from the Mojave Desert. (a)–(c) Views of a single stone. (a) The upper surface. (b) The lower surface. (c) View from one of the sides. Note the limited distribution of the photosynthetic association (greenish band). (d)–(e) Two views of a smaller stone from the same region. (d) The upper surface. (e) The lower surface. In this case the photosynthetic association nearly covers the lower surface – the rock was less than 1 cm thick, allowing light to reach the entire lower surface. (f) and (g) Two views of a third stone. (f) The upper surface. (g) The lower surface, again with an almost complete cover by the hypolithic association. This example is somewhat unusual because of the dark color of the stone. Upon closer examination the coloration was found to be superficial, the interior of the stone is white. Scale bars in all images represent 1 cm.

was also diverse, including representatives of several genera of filamentous cyanobacteria in addition to *Chroococcidiopsis* (Tracy et al., 2010).

In more arid regions, however, the diversity decreases sharply. In both the Atacama (Warren-Rhodes et al., 2006), and the arid regions of China (Pointing et al., 2007), only cyanobacteria with a *Chroococcidiopsis*-like morphology have been observed, although molecular techniques indicate the possible presence of filamentous *Phormidium*-like cyanobacteria at colder or wetter sites. The percent abundance of hypolithic communities on suitable rocks is also moisture-dependent. In the relatively mild Mojave Desert, nearly 100% of quartz pebbles are colonized by hypoliths (Schlesinger et al., 2003). In the nearby hyperarid desert of Baja California, in contrast, only between 26 and 38% of quartz stones were colonized (Heckman et al., 2006). This shift is in keeping with extensive studies along a moisture gradient in the Atacama Desert (Warren-Rhodes et al., 2006). Here, 27.6% of quartz pebbles were colonized at the “moist” Copiapo end of the transect, while at the dry end of the transect, near Yungay, only 3 out of 3723 quartz pebbles were colonized. Thus, the hyperarid core of the Atacama appears to be near the dry limit of metabolic activity for both soil and lithic microorganisms. This makes the presence of what appears to be an active and extensive cryptoendolithic association in evaporites near Yungay even more intriguing (Wierzbos et al., 2006).

Recently, the source of inocula for hypolithic associations has become a topic of special interest in the context of the biogeography of desert microorganisms. According to one school of thought, microorganisms do not exhibit a true biogeography since, because of their small size and assumed ease of dispersal, they do not face geographic barriers of the same magnitude as those encountered by macroscopic organisms. As succinctly stated by Baas Beeking (1934), “alles is overall: maar het milieu selecteert” (“everything is everywhere, but the environment selects”). If this hypothesis is true, we should expect to see (1) in regions where not all suitable stones are colonized, the distribution of colonized stones should reflect local differences in the environment and not sources of inocula; (2) the hypolithic to contain a subset of the types of microorganisms present in the surrounding soils, the subset selected by the unique environment found on the undersurface of the stone; and (3) a degree of global consistency in the structure of association in similar types of deserts.

The first of these was tested in the Atacama Desert in Chile (Warren-Rhodes et al., 2007a) and in the Taklimakan and Qaidam Basin deserts in western China (Warren-Rhodes et al., 2007b,c). In both cases, clustering of colonized stones was observed, not the random pattern expected from Baas Beeking’s hypothesis. In the Atacama Desert, clustering correlated well with rock size and

microtopography, both related to small-scale differences in moisture availability. Large rocks, as discussed previously, capture and retain more moisture, and are, therefore, more suitable for colonization. Slight depressions and elevations can also increase moisture availability; at one site 90% of colonized stones were located on a microtopographic high, where moisture from fog was presumed to be higher (Warren-Rhodes et al., 2007a). In this case the observed clustering actually mapped the location of favorable microclimates, where the habitat could, indeed, select. In western China, microtopographic data was not available, so small scale changes in microclimate could not be correlated with clustering. Instead, small scale dispersal from an initial colonized stone to surrounding stones was invoked to explain the existence of clusters of colonized stones (Warren-Rhodes et al., 2007b,c).

Surprisingly few studies have compared the hypolithic association with the microbiota in the surrounding soils. The diversity of cyanobacteria associated with hypolithic environments in semi-arid northern Australia does suggest some may be part of the larger biological soil crust association in the same area (Tracy et al., 2010). When direct comparisons have been made, there are consistent differences between the two associations. For example, in Namibia hypolithic associations were dominated by cyanobacteria (*Chroococcidiopsis*) while soil systems were dominated by actinobacteria (Makhalanyane et al., 2013a,b). Similar results were found in Antarctica in Beacon Valley (Wood et al., 2008), McKelvey Valley (Pointing et al., 2009), and Meirs Valley (Khan et al., 2011; Makhalanyane et al., 2013a,b; Wood et al., 2008). These findings support the idea that the hypolithic environment provides a selective filter of the microbial community. Somewhat surprising was the fact that cyanobacteria were not detected in the soils of the drier Beacon and McKelvey valleys (Pointing et al., 2009; Wood et al., 2008); presumably, the organisms were present, but at such low numbers that they were not detected by the techniques used. Some of the heterotrophic bacteria from lithic habitats were also not detected in soils. In Meirs Valley, there is some evidence for successional stages in the hypolithic association (Makhalanyane et al., 2013a,b).

The presence of hypolithic associations dominated by members of the genus *Chroococcidiopsis* in hot and cold deserts from around the world permitted Bahl and his colleagues to analyze distribution global distribution patterns and relationships (Bahl et al., 2011). Their findings indicate the presence of three distinct clades within the genus, one adapted to cold deserts, the other two adapted to hot deserts, and that the three groups have been evolutionarily separated for a long period of time. Within each clade there is some evidence for a degree of regional grouping of phylotypes, especially within the hot desert clades. This would suggest that dispersal between regions may be limited, at least over short periods of time. However, genetic differences between variants of *Chroococcidiopsis* were not significantly related to geographic distance on a global scale (Bahl et al., 2011), in keeping with the basic ideas of Baas Becking.

Adaptations to the Environment

All desert microorganisms are subjected to extended periods in a desiccated, metabolically inactive state. However, in this inactive state, individual cells are subject to a variety of chemical and physical insults, resulting in damage that cannot be repaired until metabolism restarts. If the damage incurred while in the inactive state is too great, the cell is unable to make repairs fast enough, and dies (Walters et al., 2005). At the same time, the association as a whole is subject to losses by erosion and predation that cannot be replaced until cellular reproduction restarts. Therefore, any feature tending to prolong the periods of activity or to help the cell survive the periods of inactivity in a desiccated state would be adaptive. A number of such features have been identified (Brown, 1990; Potts, 1994; Bewley, 1995; Wynn-Williams, 2000; Hohmann, 2002; Grant, 2004; Cox and Battista, 2005). The principal adaptations are summarized below, following a brief review of the nature of the problem.

The Concepts of Water Activity and Water Potential

The net movement of water across a cell boundary is governed by the related concepts of water activity and water potential. Water activity (a_w) is a measure of the concentration of water in a solution, as modified by the type of solutes present in the solution. It is derived from a modification of Raoult's law relating the vapor pressure of a solution (p) to the vapor pressure of the pure solvent (p_0). In the ideal case, both a_w and p/p_0 would equal the mole fraction of water (N_w) defined as $n_w/(n_w+n_s)$, where n_w is the number of moles of water and n_s is the number of moles of all solutes in the system (the treatment here follows that of Brown (1990) and Potts (1994)). In reality, unless the solutions are very dilute, the solutes interact with water, necessitating the inclusion of an empirical coefficient (γ_s). The water activity is then defined as

$$a_w = p/p_0 = \gamma_s n_w / (n_w + n_s) = \gamma_s N_w$$

The chemical potential of the water (μ_w) is given by

$$\mu_w = \mu_w^\circ + RT \cdot \ln(a_w) + V_w P + z_w F E + m_w g h$$

where μ_w° is the chemical energy of water under standard conditions (J mol^{-1}), R is the universal gas constant ($\sim 8.31447 \text{ J mol}^{-1} \text{ K}^{-1}$), T is the temperature in Kelvin, V_w is the change in volume associated with a change in the amount of water ($\sim 1.8 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}$), P is the hydrostatic pressure (N m^{-2}), z_w is the charge on a molecule of water, F is the Faraday constant ($\sim 9.6485 \times 10^4 \text{ C mol}^{-1}$), E is electrical potential (J C^{-1}), m_w is the molar mass of water ($\sim 1.8 \times 10^{-2} \text{ kg mol}^{-1}$), g is the acceleration due to gravity

($\sim 9.8 \text{ m s}^{-2}$), and h is the height of the cell (m). The electrical term can be ignored because the charge on a molecule of water (z_w) is negligible. The gravitational term can also be ignored because of the small size of the cells. The chemical potential then reduces to

$$\mu_w = \mu_w^\circ + RT \cdot \ln(a_w) + V_w P$$

which can be rewritten as

$$(\mu_w - \mu_w^\circ)/V_w = (RT \cdot \ln(a_w))/V_w + P$$

This equation leads to the definition of the water potential (ψ) of the system as

$$\psi = \frac{(\mu_w - \mu_w^\circ)}{V_w}$$

with units in terms of pressure (N m^{-2} or pascals). In this derivation, the water potential is the sum of two separate potentials, one based on the hydrostatic pressure (P), the other based on the chemical activity of water ($RT \cdot \ln(a_w)/V_w$). Conceptually, the water potential can be broken into additional terms, as appropriate. A typical formulation gives the total water potential (Ψ) as

$$\Psi = \psi_\pi + \psi_p + \psi_m + \psi_g$$

where ψ_π is the osmotic potential and refers to part of the water potential associated with dissolved substances in the system, ψ_p is the pressure potential and refers to part of the water potential associated with hydrostatic pressure, ψ_m is the matric potential and refers to part of the water potential associated with the interaction of water molecules with surfaces and interfaces, and ψ_g is the gravitational potential and refers to part of the water potential associated with gravitational forces.

A simple example may be instructive. Suppose a cell is suspended in seawater so that the external matric and gravitational potentials are negligible, and that the external hydrostatic pressure (ψ_p) is 1 atm (1.01325 bars or $1.01325 \times 10^5 \text{ Pa}$) directed inward. Because the activity of seawater at 25°C is 0.9806, the external osmotic potential (ψ_π) is $-2.70 \times 10^6 \text{ Pa}$ (-2.70 MPa); the negative sign indicates that the “pressure” is directed outward. The total water potential experienced by the cell ($\Psi_{\text{environment}}$) is given by $\psi_\pi + \psi_p = -2.6 \text{ MPa}$. At equilibrium, the total internal water potential of the cell (Ψ_{cell}), which equals the sum of the internal osmotic, hydrostatic, and matric potentials, would be the same, although none of the individual internal potentials would necessarily match any of the individual external potentials. If that same cell were now plunged into pure water ($a_w = 1.0$), $\Psi_{\text{environment}}$ would increase to $+0.1 \text{ MPa}$, while Ψ_{cell} would start at -2.6 MPa . Such an energy differential cannot be maintained. Water would begin to flow down the energy gradient into the cell. The additional water would raise the mole fraction and water activity within the cell, thereby bringing ψ_π closer to 0; it is also possible that some of the solutes may be lost. At the same time, the increased volume of water would correspond to an increased hydrostatic pressure directed outward. If the cell membrane and/or cell wall can withstand the increased hydrostatic pressure without rupturing, the cell will eventually come to a new equilibrium, with Ψ_{cell} again equal to $\Psi_{\text{environment}}$. Of course, if the cell were moved to more concentrated seawater, with a salinity of 70‰ instead of 35‰ and a water activity of ~ 0.96 , $\Psi_{\text{environment}}$ would decrease to -5.82 MPa , and water would flow out of the cell until the new equilibrium is reached.

Seawater would represent an environment with relatively constant, even if reduced, water activity. Of course, seawater, even double-strength seawater, does not constitute a dry environment and a wide range of microorganisms can survive there without major modification. More relevant environments would be found in hypersaline lakes and salinas, seawater-based evaporites ($a_w \sim 0.75$) or in cereals, candy and other confectionaries, and dried fruits ($a_w \sim 0.70$). Organisms living in these habitats would be subjected to chronic conditions of low water potential and may even be considered to be under chronic water stress. The constancy of the stress allows for some degree of predictability and biological accommodation. Even so, there are only a limited number of microorganisms capable of growing at water activities below 0.85; only two, the yeast *Zygosaccharomyces rouxii* and the filamentous ascomycete *Xeromyces bisporus*, are capable of growth at water activities below 0.70 (Grant, 2004). Terrestrial microorganisms, especially subaerial and desert forms, face a much more difficult moisture environment. The water activity of the external environment, roughly equivalent to the relative humidity of the air divided by 100 (see Dose, 2002), is not constant, but can vary between lows near 0.10 and highs near 1.00, all within a single day. Upshifts in the external water activity due to changes in the relative humidity are ameliorated somewhat by the slow pace of the diffusion of the water molecules in the air. When rains appear, however, the cells are suddenly plunged into a liquid medium with a much higher water potential. This sudden shift creates an acute stress not experienced by the food- or evaporite-inhabiting microorganisms.

Impacts of Low Water Activity on Unicellular Organisms

The effects of low water activity on cellular and macromolecular structure have been reviewed extensively by Potts (1994), Alpert (2005), Crowe and Crowe (2002) and Dose (2002) provide additional insights in their more recent reviews. Here we provide a brief summary of their major findings.

The irrefutable feature of exposure to low water activities and low water potentials is the removal of water from the cell. This process was first closely observed by Koga et al. (1966) in the desiccation tolerant yeast *Saccharomyces cerevisiae*. They identified four distinct states for intracellular water based on the total water content. In the initial state, the “solution domain,” water is free-flowing

and metabolic reactions are still possible, albeit at possibly reduced rates. Once a certain water content is reached, ~20% in *S. cerevisiae*, the cell enters what is called a “gel domain,” where water molecules no longer form a continuous solvent and metabolic activity ceases. Further reductions in water content lead to two additional states distinguished by how tightly the remaining water is bound.

These decreases in water content are accompanied by changes in the structure of the phospholipid bilayer (Crowe and Crowe, 1992, 2002; Dose, 2002). As the number of water molecules decreases, the hydration state of the individual molecules forming the bilayer changes, leading to an increase in the temperature at which the membrane changes from the biologically important liquid crystalline state to the gel state (Crowe and Crowe, 2002). Because of these changes, in the dehydrated state the membrane components are in the gel state at physiological temperatures (Crowe and Crowe, 2002). As water is added back into the system, and the gel–liquid crystalline transition temperature drops back to physiological levels, there is a transient state when the membrane is part liquid crystalline and part gel. Such two-part systems are highly permeable to small molecules (Potts, 1994; Crowe and Crowe, 2002). For non-desiccation-resistant microorganisms, these changes in the cell membrane may be the primary cause for cell death during freeze-drying (Crowe and Crowe, 2002).

Presumably, changes in the hydration states of individual proteins, similar to those experienced by molecules of the bilayer, will occur as the amount of water decreases. Such changes could impact the three-dimensional structure of the proteins, especially where hydrophobic interactions are involved, causing potentially irreversible denaturation (Dose, 2002). How much damage is caused by this mechanism is not clear (Potts, 1994). For the desiccation-tolerant cyanobacteria *N. commune*, proteins involved in lipid biosynthesis and in glycerol, sulfate, and phosphate uptake appear to be undamaged, while phycobiliproteins involved in light harvesting are rapidly degraded (Potts, 1985, 1994).

In contrast with the case for proteins, there is clear evidence that DNA is a major target of desiccation-induced damage (Potts, 1994). Conformational changes accompanying the loss of hydration shells allow the formation of crosslinks between the phosphodiester group of DNA and a protein-bound OH group (Dose, 2002). These crosslinks result in single-strand and double-strand breaks in the DNA, as many as ten breaks per single-strand genome after 12 min of drying in the desiccation-sensitive strain *Escherichia coli* K-12 AB 1157 (Dose et al., 1992; Dose, 2002). Even desiccation-resistant *Bacillus subtilis* spores and *Aspergillus ochraceus* conidia display increasing amounts of DNA–protein crosslinking during exposure to desiccation (Bieger-Dose et al., 1992). Depurination of individual nucleotides may also be a significant source of DNA lesions (Dose, 2002), with the rate for desiccated samples of *N. commune* estimated to be sufficient to depurinate 1% of the genome in 10 years (Potts, 1994).

The presence of reducing sugars and O₂ can increase the amount of damage sustained by all components. Maillard reactions, a series of browning reactions between reducing sugars and amino acids, may occur, thereby damaging proteins, although the rate would be expected to be low in the desiccated state (Dose, 2002). There is evidence that reducing sugars can also interact with DNA and membranes (Dose, 2002). These reactions would also occur in hydrated cells, but in the hydrated case repair mechanisms not available in the desiccated state would be in operation. It is also expected that active species of oxygen (O₂[•], H₂O₂, and OH[•]) will form in drying cells under the influence of light (Potts, 1994). The presence of appreciable amounts of these species would lead to increased rates of single-stranded breaks in DNA, oxidation of proteins, and peroxidation of lipids, all of which cannot be repaired in the inactive state (Potts, 1994).

Adaptations to Arid Environments

As mentioned previously, a variety of adaptations to arid environments can be identified. In the following discussion, these are grouped according to which feature of the environment the adaptations appears to address. Note, however, that this is only a loose grouping and that many of these adaptations serve multiple purposes. For example, the presence of a sheath can serve to retard water loss, maintain cell membrane integrity, and protect against photodamage (Potts, 1994; Table 2).

Adaptations to Prolong the Period of Activity

Higher plants and terrestrial animals remain active in desiccating environments through the formation of complex multicellular structures with essentially watertight surfaces. This option is not open to unicellular forms. However, they can use extracellular structures to accomplish the same end, albeit not as efficiently. For example, nearly all terrestrial cyanobacteria, many eukaryotic algae, and the cryptoendolithic black fungi from Antarctica form extensive mucilaginous sheaths, as much as 98% of which may be water (Friedmann and Galun, 1974; Grilli Caiola et al., 1996; Potts, 1994; Wynn-Williams, 2000; Selbmann et al., 2005). This water reserve can prolong the period of activity under desiccating conditions from several hours to a few days (Shephard, 1987; Nienow and McKay, 2000). The sheaths may also control the rate at which water enters the cell after dehydration, preventing the resumption of metabolic activity until there is sufficient moisture in the environment to sustain activity for a prolonged period of time (Williams et al., 2014). In soil crusts and mats, the polysaccharide sheaths may form a physical barrier, which serves to retard evaporation and retain moisture in the lower levels (Davey and Clarke, 1992; Belnap, 2006). Soils and the porous rocks and stones of the cryptoendolithic habitat may also serve as water reservoirs for the community (Friedmann et al., 1987, 1993a,b; McKay et al., 2003; Omelon et al., 2006; Warren-Rhodes et al., 2007a,b,c), and help to capture and retain water at low water activities either through their physical or through their chemical structure (Palmer and Friedmann, 1990; Rothschild et al., 1994; Wierzbos et al.,

Table 2 A partial list of the major innate adaptations to the dry environment. Examples are for illustrative purposes only; the specific adaptations of most microorganisms found in dry environments have not been investigated

Adaptation	Function(s)	Examples
Mucilaginous sheaths (extracellular polysaccharides)	Water storage; cell membrane stabilization	Nearly all terrestrial cyanobacteria, including <i>Chroococcidiopsis</i> , <i>Gloeocapsa</i> , <i>Microcoleus</i> , <i>Scytonema</i> , and <i>Nostoc</i> ; many chlorophytes including <i>Hemichloris</i> ; black fungi <i>Friedmanniomyces</i> , <i>Cryomyces</i>
Production of compatible solutes	Cell membrane stabilization; stabilization of the tertiary structure of proteins and DNA	<i>Chroococcidiopsis</i> , <i>Nostoc</i> ; the fungi <i>Zygosaccharomyces</i> , <i>Xeromyces</i>
Photoprotective pigments in sheaths and walls	Absorption of UV and high-energy visible light	Many cyanobacteria including <i>Chroococcidiopsis</i> , <i>Gloeocapsa</i> and <i>Scytonema</i> (scytonemin and MAA's); black fungi (melanin)
Carotenoid production	Quenching of free radicals	<i>Deinococcus</i> , cyanobacteria such as <i>Nostoc</i> ; many chlorophyte algae including <i>Trentepohlia</i> , <i>Haematococcus</i> , <i>Chlorella</i> spp.
Efficient DNA repair mechanisms	Repair the damage incurred during desiccation or exposure to radiation	<i>Deinococcus</i> , possibly the cyanobacterium <i>Chroococcidiopsis</i>
Multiple copies of the genome	Provide multiple copies of essential genes, serve as template for DNA repair	Possibly <i>Chroococcidiopsis</i> , <i>Nostoc</i>
Spore formation; encystment	Specialized cells able to resist dry conditions	Endospore-forming bacteria, members of the Actinobacteria; most fungi
Motility	Avoidance of excessive insolation, possible movement toward higher concentrations of water	<i>Microcoleus</i> , <i>Oscillatoria</i> , and some other filamentous cyanobacteria; some flagellated eukaryotic algae

2010, 2012; Warren-Rhodes et al., 2013). Of special interest in this respect is the role mineral deliquescence plays in controlling the metabolism of the endolithic association living in halites in the Atacama Desert (Davila et al., 2008, 2013).

The hypolithic association enjoys a particularly favorable habitat in this regard. The dominant microorganisms, usually a member of *Chroococcidiopsis* or *Gloeocapsa* (Friedmann and Galun, 1974; Büdel and Wessels, 1991), form thick sheaths extending some distance from the surface of the stone. In addition, the nonporous stones overlying the association serve as efficient moisture barriers. Therefore, it is not surprising that the moisture content in the soil beneath the association is often much higher than in the surrounding soil (Cameron and Blank, 1966; Broady, 1981b; Smith et al., 2000; McKay et al., 2003). This effect can be enhanced by the thermal properties of the stone. Large stones can generate thermal gradients within the soil that result in the net movement of water vapor through the soil to the hypolithic environment; in effect, the lower surface of the stone acts as a water collection system (Jury and Bellantuoni, 1976a,b). However, for the water collection system to be effective, there must be significant quantities of moisture available in the soil. Therefore, it is not too surprising that attempts to measure this effect in the core of the Atacama have been unsuccessful (McKay et al., 2003). The upper surfaces of stones are also more efficient dew, fog, and mist collectors than soil surfaces. This may account for the presence of desert varnish communities in semiarid and arid regions. It is also possible for the collected water to pool on the surface and then trickle off the surface to moisten the soil around the edges and just below the stone, thereby supporting the hypolithic association. The effect is enhanced with large, nonporous stones, explaining the preference for colonization of larger quartz stones, especially in the perolithic habitat, in hyperarid deserts (Warren-Rhodes et al., 2007a,b,c; compare McKay et al., 2003; Warren-Rhodes et al., 2013).

A number of eukaryotic algae are capable of absorbing sufficient water vapor when the relative humidity is high to maintain some level of metabolic activity (see Lange et al., 1990; Nienow, 2002). Included in these are a number of forms commonly found in desert environments, including strains of the green alga *Stichococcus* (Nienow and McKay, 2000). It is generally believed that this ability is not present in cyanobacteria or other prokaryotic organisms (see Nienow, 2002). However, the desert crust cyanobacterium *Microcoleus sociatum* may be able to use water vapor at relative humidity in excess of 95% (Büdel, 1994). The mechanism behind this ability is unknown. In the case of *Microcoleus*, it may result from the structure of the filament – several trichomes within a communal sheath. The compact arrangement could lead to the formation of liquid water within small capillaries. In the case of unicellular forms such as *Stichococcus* or the subaerial taxon *Apatococcus*, it is presumed to be related to the buildup of compatible solutes in the cell (see below), although this is yet to be tested.

Some of the filamentous cyanobacteria present in desert crusts are known to be mobile during wet conditions, rising to the surface of the soil and causing a brief “greening” of the desert and then retreating back into the soil to take up residence a few millimeters below the surface (Brock, 1975; Dor and Danin, 2001; Belnap, 2006). In *Microcoleus*, the movement is apparently caused by a combination of physical exclusion of the living trichomes from the polysaccharide sheath as it swells with water and typical cyanobacterial gliding motility (Dor and Danin, 2001). In other cases, gliding motility alone is sufficient. Much of the movement appears to be directed upward toward the surface of the soil, possibly in a phototactic response, possibly as part of a random process (Pringault and Garcia-Pichel, 2003). As the soil dries, at least some members of the association track the moisture gradient back into the soil, in a hydrotactic response (Garcia-Pichel and Pringault, 2001; Pringault and Garcia-Pichel, 2003).

Adaptations to Survive Desiccation

Even with the most efficient means of prolonging water availability, desert microorganisms will become desiccated. At present, little is known of the mechanisms by which desert microorganisms survive the drying process. The first step seems to be the formation of some sort of compatible solute. Compatible solutes are low-molecular-weight organic compounds that can serve to lower the osmotic potential and, therefore, the total water potential within the cell while maintaining cellular and molecular integrity. A large number of different types of molecules have been implicated as compatible solutes, including polyols, sugars and sugar derivatives, betaines, some amino acids and amino acid derivatives, and ectoines. Trehalose and sucrose seem to be particularly important in organisms subjected to extreme water stress; thus, it is not surprising that desert *Chroococcidiopsis* sp. and *N. commune* are both known to accumulate trehalose and sucrose under conditions of water stress (HersHKovitz et al., 1991; Hill et al., 1997; Sakamoto et al., 2009). Trehalose and sucrose both seem to work by stabilizing cell membranes by replacing the water bound to phosphate groups, and thereby depressing the phase transition temperature of desiccated membranes to physiological temperatures, and by preventing the fusion of membrane vesicles (Crowe and Crowe, 1992; Potts, 1994, 1999); they may also stabilize protein and DNA structure (Potts, 1994). The extracellular polysaccharides may work in the same way to stabilize the outer membranes of bacteria or the outer layers of the cell membrane of other organisms. It is interesting, in this respect, to note that cyanobacteria with intact, lamellated sheaths have greater viability than those without (Grilli Caiola et al., 1996); similar sheaths have been noted in endolithic biofilms (de los Rios et al., 2007).

Adaptations to Reduce the Damage While in the Desiccated State

Phototrophic microorganisms are all subject to the accumulation of photooxidative damage resulting from the reduction of oxygen and other molecules by photosystems only partially active in the desiccated state (Smirnov, 1993; Lao and Glazer, 1996; Gray et al., 2007). In addition, all desert microorganisms are subject to the accumulation of damage caused by UV light. Therefore, the existence of a variety of mechanisms to reduce overall exposure to light is not surprising. Simplest among these is the growth in low-light environments. As discussed previously, both hypolithic and cryptoendolithic microorganisms inhabit environments where the maximum photon flux is several orders of magnitude lower than that of the soil or rock surface. Motile crust-forming cyanobacteria, for example, *Microcoleus* and *Oscillatoria*, form layers several millimeters below the surface of the soil during dry conditions (Dor and Danin, 2001; Pringault and Garcia-Pichel, 2003); here, again, the photon flux is much reduced. Nonmotile members of desert crusts, for example, *Scytonema*, and cryptoendolithic lichens and cyanobacteria inhabiting the upper layers of the association usually form some sort of photoprotective pigment. Many desert and subaerial cyanobacteria produce the brown sheath pigment scytonemin and/or water-soluble mycosporine-like amino acids, both of which are known to provide some degree of protection against UV and high-energy visible light (Garcia-Pichel and Castenholz, 1991, 1993; Ehling-Schulz and Scherer, 1999; Oren and Gunde-Cimerman, 2007). Many lithophytic and lichen-forming fungi produce melanin, mycosporine and mycosporine-like amino acids, and/or carotenoids (Gorbushina et al., 2003; Onofri et al., 2004; Selbmann et al., 2005; Oren and Gunde-Cimerman, 2007). Terrestrial eukaryotic algae generally lack colored sheaths and walls. However, some species, notably members of the genera *Chlamydomonas*, *Chlorella*, *Chlorococcum*, *Haematococcus*, and *Trentepohlia*, have the potential to accumulate oil droplets colored by the carotenoids astaxanthin and/or zeaxanthin under high light, low water, or low nutrient conditions (Ho et al., 1983; Adams et al., 1993; Bidigare et al., 1993; Remias et al., 2005). These may serve to shield the cells from excess light, in a manner similar to the colored sheaths of cyanobacteria (Demmig-Adams and Adams, 1992; Gorton et al., 2001; Remias et al., 2005). They may also serve to scavenge the reactive oxygen species associated with photooxidative damage (Demmig-Adams and Adams, 1992; Trebst, 2003; Remias et al., 2005; Holzinger and Karsten, 2013). Ascorbic acid, glutathione and α -tocopherol in the plastid serve similar purposes in higher plants and at least some eukaryotic algae (Demmig-Adams and Adams, 1992; Trebst, 2003; Remias et al., 2005; Holzinger and Karsten, 2013). Changes in the pigment complement within chloroplasts may enhance the operation of the xanthophyll cycle, a mechanism for the thermal dissipation of light energy captured by the light harvesting complexes, thereby reducing the number of reactive oxygen species created (Demmig-Adams and Adams, 1992). Intracellular pools of manganese ions may serve to block the formation of iron-dependent reactive oxygen species (Daly, 2009).

Adaptations Leading to a Quick Recovery

The final set of adaptations seen in desert organisms are those leading to a quick recovery from damage associated with desiccation, especially damage to the DNA. These have been best studied in *Deinococcus radiodurans*, primarily in regard to damage from ionizing radiation (see Cox and Battista, 2005; Daly, 2009). Several mechanisms have been implicated, including the presence of multiple copies of the genome within individual cells, delays in DNA replication until damage has been repaired, physiologic responses including the induction of a suite of genes following exposure to desiccation and ionizing radiation, protein-based protection of the broken ends of the DNA molecule, RecA-independent double-strand break repair, and novel forms of RecA repair mechanisms. The multiple copies of the genome reduce the risk of inactivating all copies of individual genes at the same time. They also provide reserve of information that can be used to repair damaged sequences. Not all of the stress-induced proteins have been assigned functions, but at least five have been implicated in genome repair. One of these, DdrA, binds to the 3' end of single-stranded DNA, protecting it from degradation by nucleases in vitro. Presumably, within desiccated or irradiated cells it would bind to the broken ends of the DNA, protecting them until repair can be accomplished. It is also worth noting that *D. radiodurans* is known to

accumulate manganese ions, which can protect the repair proteins (and others) during desiccation or exposure to ionizing radiation enhance recovery after the stress has been removed (Daly, 2009).

How far the mechanisms used by *Deinococcus* can be applied to other members of the desert community is not clear. Desert strains of *Chroococcidiopsis*, also known to be radiation-resistant, are postulated to rely on multiple genome copies, but this has not been investigated in detail (Billi et al., 2000). *N. commune* is thought to rely more on protective mechanisms, high trehalose concentrations, in particular, to reduce the amount of damage occurring during desiccation. Clearly, more research is necessary in this area.

Relevance to Astrobiology

The Search for Life on Mars

According to the currently accepted theory, about 3.8 billion years ago conditions on Mars included flowing liquid water and surface temperatures above zero (McKay, 1993). While these conditions did not last long, it is possible that they were of sufficient duration that life could have arisen independently on Mars at about the same time that it arose on Earth. In addition, much of the surface of Mars, unlike the surface of Earth, remains relatively unchanged since that period. Therefore, Mars may have the best record of the origin of life on Earth-like planets (McKay, 1993). One focus of astrobiological research is to develop strategies and techniques for the in situ search for indications of the remnants of these early stages of life. Dry environments on Earth are useful in this context for two reasons. First, as the environment on Mars changed, the surface would have become increasingly colder and drier, approximating the conditions in arid and hyper-arid regions currently in existence on Earth. These regions, therefore, serve as models of the types of ecosystems that may have been present during the final stages of life on Mars. The continued development tools and techniques for the morphological and chemical analysis of the microbial associations found in the arid regions Earth is clearly central to the development of similar tools and techniques for the search for the remnants of life on Mars (see, e.g., Perry and Kolb, 2004; Warren-Rhodes et al., 2007d).

Interplanetary Exchange of Microorganisms – Testing Panspermia

Allen Hills 84001 (ALH 84001), a meteorite thought to have originated on Mars, gained notoriety when it was claimed that it contained evidence of extra-terrestrial life (McKay et al., 1996). While the initial claims remain, at best, controversial, the discussions that ensued led to a renewed interest in panspermia, the theory that organisms can be transferred between planets by natural processes. The current form of the theory, lithopanspermia, suggests that rocks containing microorganisms are ejected from a planetary body, such as Mars, by the impact of a large asteroid or comet. The rocks, with their microbiota relatively intact, eventually reach another planet where the microorganisms take up residence. Because the organisms would have to be present in the interior of the rock before ejection from the planetary body, endolithic communities, especially those from arid regions with a presumed level of pre-adaptation for withstanding the conditions associated with space travel, are considered candidates for testing this theory.

For lithopanspermia to be successful, the microbiota must survive the initial ejection from the planetary body, the subsequent journey through space, and re-entry on a second planetary body (Horneck et al., 2010). All three of these have been tested directly using cryptoendolithic cyanobacteria and cryptoendolithic associations, with, at best, mixed results. In a test of the initial ejection phase, dried cells of *Chroococcidiopsis* were placed between two gabbro plates and then exposed to shocks mimicking the impact of a meteorite (Horneck et al., 2008). The cells were able to survive shocks of up to 10 GPa; higher shocks resulted in mechanical damage to the cells. While encouraging, this is at the low end of estimates of the shocks experienced by examples of Martian meteorites recovered on Earth (Horneck et al., 2008). It should be noted, however, that other microorganisms, including at least one species of lichens and bacterial spores, could withstand much greater shocks, including shocks sufficient for ejection (Horneck et al., 2008). In a separate set of experiments, survival during transit was tested by exposing desiccated pieces of Antarctic sandstones colonized by cryptoendolithic associations to space conditions and to simulated Mars conditions aboard the International Space Station (Scalzi et al., 2012). After one and a half years, the samples were returned to Earth and cultured. The investigators were able to recover only one colony of the green alga *Stichococcus* from the simulated Mars conditions and three colonies of fungus *Acaropora* from the space conditions. This is a much lower diversity than what was recovered from the control samples and much lower than present in the original samples, and suggests that presence in the cryptoendolithic habitat does not guarantee survival over years in the space environment (Scalzi et al., 2012). In a third set of experiments, the ability of *Chroococcidiopsis* to survive re-entry was tested using the European Space Agency's STONE facility. In this system, small pieces of material can be affixed to the exterior of spacecraft, near the heat shield of a FOTON re-entry vehicle near the ablation point, and exposed directly to the heat of re-entry. In an initial experiment samples of impact-shocked gneiss were inoculated with cultures of *Chroococcidiopsis* then attached to the vehicle (Cockell et al., 2007). During re-entry, the vehicle entered the atmosphere at speeds close to 8 km per hour, somewhat slower than meteorites. However, even at these slow speeds, the surface of the sample melted and all biological material was destroyed (Cockell et al., 2007). In a follow-up experiment, *Chroococcidiopsis*, piece of lichen, and bacterial endospores attached to the carrier behind a 2-cm piece of shocked gneiss instead of on the exposed surface, in order to provide some degree of protection. Again, none of the biological material survived the high-temperatures associated with re-entry, although the remains of the cells and biochemical markers were detected. This places a severe constraint on the types of endolithic associations are suitable for consideration in the context of lithopanspermia (Cockell et al., 2007).

Introduction

The first report of life in a hot environment, herein defined as being above 70°C, came from the observation of high concentrations of microbes (or 'chlorophyllless filamentous Schizomycetes') in an 89°C hot spring in Yellowstone National Park sampled in 1898. The hottest known microbes are 'hyperthermophiles', which are those organisms that grow optimally above 80°C. In hot environments, they are commonly joined by the hottest thermophiles, which are those organisms that grow optimally above 55°C. After 1980, many microbes that grow above 70°C were cultured and characterized from terrestrial geothermal environments and shallow marine vents. At the same time, microbes from deep-sea hydrothermal vents were isolated from mid-ocean spreading centers and volcanic seamounts. The advent of metagenomics and microbial community analysis has shown that hyperthermophiles and hot thermophiles are also found in other hot environments such as in petroleum reservoirs and deep marine sediments.

In general, thermophiles that grow below 70°C are found in a wide range of environments outside of the hot environments discussed herein. These include coal refuse, hot water tanks, and compost piles. Photosynthetic bacteria can grow up to 70°C and include cyanobacteria and green- and purple-sulfur bacteria. There are many spore-forming thermophiles such as *Bacillus*, *Clostridium*, and *Moorella* species; and there are thermophilic *Actinomycetes*, sulfur oxidizers, sulfate reducers, and Gram-negative aerobes such as *Thermus aquaticus*, the source of the Taq DNA polymerase. Even some *Alvinellid* polychaete worms from hydrothermal vents are known to live at temperatures of 55–60°C. However, this review focuses on those microbes that grow without sunlight and optimally above 70°C. Their growth characteristics will be described based on their metabolic function. This includes specialists such as methanogens, other autotrophs, hydrogen-producing heterotrophs, and thermoacidophiles as well as metabolic generalists from freshwater and marine environments that grow either autotrophically or heterotrophically and use numerous inorganic compounds to support their growth. The review will then discuss characteristics of hot environments, such as hydrothermal vents, hot springs, and hot sedimentary environments including petroleum reservoirs, and the organisms and geochemical processes within them.

Metabolic Functional Groups

Methanogens

Microbial methanogenesis is the largest source of methane globally with an annual production rate of 10⁹ tons. All microbial methanogenesis is catalysed by archaea and mediated by obligately anaerobic methanogens in the *Euryarchaeota*, although there is recent metagenomic evidence for possible methanogenesis in the *Bathyarchaeota* and *Verstraetearchaeota*. Methanogens are most abundant in environments where alternative terminal electron acceptors such as sulfate, nitrate, and metals are depleted. They generate methane by using hydrogen and CO₂, formate, methylated compounds, and acetate as carbon and energy sources. The *Methanococcales*, *Methanobacteriales*, and *Methanopyrales* are the Orders that have representatives with optimal growth above 70°C (Table 1). Their growth is almost entirely hydrogenotrophic (i.e., 4H₂+CO₂→CH₄+2H₂O), although a few species are capable of growth on formate. Like all methanogens, they couple methanogenesis to the Wood-Ljungdahl pathway for CO₂ fixation and energy conservation. The key enzyme in methanogenesis is methyl-CoM reductase, which serves as a genetic marker for methanogenesis in the environment (e.g., *mcrA*).

Methanocaldococcus (Fig. 1(A)) and *Methanoterris* are marine genera in the *Methanococcales* Order that grow best at temperatures of 80–88°C. *Methanocaldococcus jannaschii* is the most studied hyperthermophilic methanogen and was among the first microbes to have its complete genome sequenced. While nitrogen fixation in high-temperature methanogens is unusual, *Methanocaldococcus* strain FS406-22 is the hottest known organism capable of this process. The Order *Methanobacteriales* is divided into two Families: the *Methanobacteriaceae* and the *Methanothermaceae*. The *Methanobacteriaceae* do not grow optimally above 70°C, but does include *Methanothermobacter* species that grow best around 65°C and are common in many mildly hot environments. In contrast, all *Methanothermaceae* grow optimally at 83–88°C. Its sole genus is *Methanothermus*, whose species are the only hyperthermophilic methanogens found in terrestrial hot environments and grow up to 97°C. The Order *Methanopyrales* has the highest optimal growth temperatures of any methanogen. *Methanopyrus kandleri* is marine and the only species in the Order. It is the hottest life form known anywhere with growth under hydrostatic pressure at temperatures up to 122°C.

Table 1 Taxonomy of microbes that grow above 70°C and arranged by functional group. The genera, optimal growth temperatures, carbon sources, and electron acceptors are provided for each listed Order

Functional groups by Order	Genera	T_{opt} (°C)	Carbon sources	Electron acceptors
Methanogens				
Methanobacteriales	<i>Methanothermus</i>	83–88	A	CO ₂
Methanococcales	<i>Methanocaldococcus</i> , <i>Methanoterris</i>	80–88	A	CO ₂
Methanopyrales	<i>Methanopyrus</i>	95–100	A	CO ₂
Other obligate autotrophs				
Aquificales	<i>Aquifex</i> , <i>Balnearium</i> , <i>Caldimicrobium</i> ^a , <i>Desulfurobacterium</i> , <i>Hydrogenivirga</i> , <i>Hydrogenobacter</i> , <i>Persephonella</i> , <i>Phorcysia</i> , <i>Sulfurihydrogenibium</i> , <i>Thermocrinis</i> ^a , <i>Thermosulfidibacter</i> , <i>Thermovibrio</i> , <i>Venenivibrio</i>	70–85	A	S ⁰ , S ₂ O ₃ ²⁻ , O ₂ , NO ₃ ⁻ , Fe(III), AsO ₄ ³⁻ , SeO ₄ ²⁻
Thermodesulfobacteriales	<i>Geothermobacterium</i> , <i>Thermodesulfatator</i> , <i>Thermodesulfobacterium</i> ^a , <i>Thermosulfurimonas</i>	70–90	A	S ⁰ , S ₂ O ₃ ²⁻ , SO ₄ ²⁻ , Fe(III)
H ₂ producers				
Thermoanaerobacteriales	<i>Caldicellulosiruptor</i> , <i>Thermoanaerobacter</i>	70–75	H	H ⁺ , S ⁰ , S ₂ O ₃ ²⁻
Thermococcales	<i>Pyrococcus</i> , <i>Thermococcus</i>	80–100	H	H ⁺ , S ⁰
Thermotogales	<i>Thermotoga</i> , <i>Fervidobacterium</i>	70–80	H	H ⁺ , S ⁰
Marine generalists				
Archaeoglobales	<i>Archaeoglobus</i> , <i>Ferroglobus</i> , <i>Geoglobus</i>	70–88	A, H, FA	SO ₄ ²⁻ , S ₂ O ₃ ²⁻ , NO ₃ ⁻ , Fe(III)
Desulfurococcales	<i>Aeropyrum</i> , <i>Desulfurococcus</i> , <i>Hyperthermus</i> , <i>Ignicoccus</i> , <i>Ignisphaera</i> , <i>Pyrodictium</i> , <i>Pyrolobus</i> , <i>Staphylothermus</i> , <i>Stetteria</i> , <i>Sulfophobococcus</i> , <i>Thermodiscus</i> , <i>Thermogladius</i> , <i>Thermosphaera</i>	85–106	A, H, FA	H ⁺ , S ⁰ , S ₂ O ₃ ²⁻ , SO ₃ ²⁻ , Fe(III), NO ₃ ⁻ , O ₂
Freshwater generalists				
Thermoproteales	<i>Caldivirga</i> , <i>Pyrobaculum</i> , <i>Thermocladium</i> , <i>Thermofilum</i> , <i>Thermoproteus</i> , <i>Vulcanisaeta</i>	75–100	H, FA	O ₂ , S ⁰ , SO ₄ ²⁻ , S ₂ O ₃ ²⁻ , NO ₃ ⁻ , Fe(III), AsO ₄ ³⁻ , SeO ₄ ²⁻
Thermoacidophiles				
Acidilobales	<i>Acidilobus</i> , <i>Caldisphaera</i>	70–85	H	S ⁰
Sulfolobales	<i>Acidianus</i> , <i>Metallosphaera</i> , <i>Stygiolobus</i> , <i>Sulfolobus</i> , <i>Sulfurisphaera</i>	70–85	A, FA	S ⁰ , O ₂ , Fe(III)

^aContains some species that are facultative autotrophs.

Other Obligate Autotrophs

Other obligate autotrophs in hot environments include the *Aquificales* and the *Thermodesulfobacteriales*, which are both bacteria (Table 1). They primarily use hydrogen and sulfur compounds as their electron donor and acceptor, although there are a few facultative autotroph exceptions. The *Aquificales* grow optimally at 70–85°C and contains three Families: the *Aquificaceae*, the *Desulfurobacteriaceae*, and the *Hydrogenothermaceae*. With a few exceptions, the *Aquificaceae* are strict chemolithoautotrophs that fix CO₂ using the reductive Tricarboxylic Acid Cycle and use hydrogen, thiosulfate, and elemental sulfur as electron donors. Most are microaerophiles that use a low concentration of oxygen as a terminal electron acceptor, although sulfur compounds and nitrate can also be used as an electron acceptors. *Aquifex* uses oxygen as an electron acceptor at very low concentrations, oxidizes hydrogen, and makes water as the final product (i.e., Knallgas reaction) at temperatures up to 95°C. *Hydrogenivirga* and *Hydrogenobacter* use hydrogen, thiosulfate, and elemental sulfur as electron donors and nitrate and oxygen as electron acceptors. *Thermocrinis* forms grey and pink filamentous masses in streams that are visible to the eye. *Thermocrinis albus* produces individual filaments up to 60 µm long and can also grow heterotrophically on formate and formamide under microaerophilic conditions.

The *Desulfurobacteriaceae* are strict anaerobes and chemolithoautotrophs that couple hydrogen oxidation to the reduction of elemental sulfur, thiosulfate, sulphite, and nitrate. *Desulfurobacterium* (Fig. 1(B)) cells form filamentous masses that can be 8 cm in length. *Balnearium* only reduces elemental sulfur while *Thermovibrio* and *Phorcysia* reduce elemental sulfur as well as nitrate to ammonium.

The *Hydrogenothermaceae* are also strict chemolithoautotrophs, except for some *Sulfurihydrogenibium* that are facultative autotrophs. *Persephonella* use hydrogen, thiosulfate, and elemental sulfur as electron donors and elemental sulfur, nitrate, and oxygen as terminal electron acceptors. *Sulfurihydrogenibium* are also metabolically versatile using these compounds plus ferrous iron, arsenite, and selenite as electron donors and ferric iron, arsenate, and selenate as electron acceptors. They are important in sulfur cycling and iron mineralization. In contrast, *Venenivibrio* species grow solely using hydrogen and oxygen to make water.

The *Thermodesulfobacteriales* are mostly obligate autotrophs that grow best at 70–90°C, but a few are facultative autotrophs. *Caldimicrobium* use hydrogen or ethanol as electron donors and thiosulfate or elemental sulfur as terminal electron acceptors. Freshwater *Caldimicrobium thiodismutans* and marine *Thermosulfurimonas dismutans* grow autotrophically by disproportionation of

elemental sulfur, thiosulfate, and sulphite. *Thermosulfurimonas* fixes CO₂ using the Wood-Ljungdahl pathway. *Thermodesulfatator* are marine autotrophs that grow solely on sulfate as an electron acceptor, while *Thermodesulfobacterium* are autotrophs that reduce sulfate, sulphite, thiosulfate, or elemental sulfur. Some *Thermodesulfobacterium* species can also use organic compounds as electron donors. *Geothermobacterium* are freshwater obligate iron reducers that couple hydrogen oxidation with ferrihydrite reduction forming magnetite at temperatures up to 100°C, making them the hottest known bacteria.

Hydrogen Producers

High-temperature hydrogen producers (Table 1) use a variety of organic substrates for growth, contain an unusually high number of glycosyl hydrolases and transferases, and in some cases use energetically favorable electron carriers such as ferredoxin that help the organisms overcome hydrogen inhibition. Many of them also use sulfur compounds for growth, and produce hydrogen primarily in the absence of these electron acceptors. They can grow syntrophically with hydrogenotrophs through interspecies hydrogen transfer.

Within the *Thermoanaerobacteriales*, *Caldicellulosiruptor* and *Thermoanaerobacter* are bacteria that grow optimally at 70–75°C with similar fermentation and hydrogen generation pathways. *Caldicellulosiruptor* species degrade many organic compounds including lignocellulosic substrates and have high hydrogen yields. They are studied extensively for potential biofuel production. *Thermoanaerobacter* is saccharolytic, but not cellulolytic, and also reduces thiosulfate and elemental sulfur. Both genera use the Embden-Meyerhof pathway for sugar catabolism and generate hydrogen using NADH-dependent hydrogenases. Hydrogen production is only possible at very low hydrogen concentrations. When hydrogen concentrations increase, there is a shift to lactate production in *Caldicellulosiruptor* and ethanol in *Thermoanaerobacter*. In the *Thermotogales*, *Thermotoga* are bacteria that grow best at 70–80°C and catabolize sugars using the Embden-Meyerhof pathway to produce acetate, lactate, ethanol, CO₂, and hydrogen. They use a bifurcating enzyme, ferredoxin:NADH oxidoreductase, for hydrogen generation and generate lactate when inhibited by hydrogen. *Thermotoga* will preferentially use elemental sulfur over protons as its terminal electron acceptor when it is available.

The *Thermococcales* are archaea in the *Euryarchaeota* that grow optimally at 80–100°C and either require or are stimulated by elemental sulfur. They are the most studied hyperthermophiles due to their industrial applications and ease of growth. They are often the source of DNA polymerases used for the polymerase chain reaction (PCR) and in vitro DNA replication. They all use

a modified archaeal Embden-Meyerhof pathway for sugar catabolism that uses ADP-dependent rather than ATP-dependent hexokinases and phosphofructokinases as well as a ferredoxin-dependent glyceraldehyde-3-phosphate oxidoreductase in place of NADH-dependent glyceraldehyde-3-phosphate dehydrogenase and ATP-producing 3-phosphoglycerate kinase. This results in no net ATP production in this pathway. They also use ferredoxin-dependent oxidoreductases to catabolize peptides that are linked with NADH-producing glutamate dehydrogenase. *Pyrococcus furiosus* grows optimally at 100°C and is one of the most thoroughly studied hyperthermophiles. It preferentially reduces elemental sulfur to hydrogen sulphide using a soluble heterodisulfide reductase but also makes hydrogen in the absence of sulfur. It uses a ferredoxin-dependent hydrogenase on its membrane to produce hydrogen and generate a H^+/Na^+ gradient that is used for oxidative phosphorylation and ATP generation on the membrane. It also has a soluble NADH-dependent hydrogenase that is used for biosynthesis reactions. *Thermococcus* are widespread in hot marine environments with over 30 species in culture and more than 20 of their genomes sequenced. They also preferentially reduce elemental sulfur to hydrogen sulphide and in some cases protons to hydrogen gas. In addition to the ferredoxin- and NADH-dependent hydrogenases found in *Pyrococcus*, some *Thermococcus* also have membrane-bound formate- and CO-dependent hydrogenases that expand the hydrogen production and H^+/Na^+ translocation capabilities of these organisms.

Marine Generalists

There are two Orders of marine generalist that are both archaea: the *Archaeoglobales* in the *Euryarchaeota* and the *Desulfurococcales* in the *Crenarchaeota* (Table 1). They are obligate heterotrophs or facultative autotrophs that use a wide range of electron donors and acceptors. The *Archaeoglobales* reduce sulfate, thiosulfate, iron, and nitrate; although elemental sulfur inhibits their growth. *Archaeoglobus* are facultative autotrophs or heterotrophs that reduce sulfate and thiosulfate to hydrogen sulphide. In contrast, neither *Ferroglobus* nor *Geoglobus* can reduce sulfate. *Ferroglobus* species can oxidize Fe(II), hydrogen, sulphide, acetate, and aromatic compounds and reduce nitrate, thiosulfate, Fe^{3+} -citrate, and ferrihydrite. *Geoglobus* species grow autotrophically by hydrogen oxidation and are obligately dependent on either Fe^{3+} -citrate or ferrihydrite as terminal electron acceptors.

The *Desulfurococcales* are comprised of two Families: the *Pyrodictaceae* and the *Desulfurococcaceae*. The *Pyrodictaceae* grow best at 90–106°C and often have unique cell structures that vary from coccoid to disk-shaped and the cells can form a network of cannulae that are tubular structures composed of glycoprotein subunits that connect the cells. They are autotrophs, facultative autotrophs, and heterotrophs that sometimes require hydrogen for growth and use a variety of terminal electron acceptors such as elemental sulfur, thiosulfate, nitrate, oxygen, and ferrihydrite. *Pyrolobus fumarii* is a strict H_2 oxidizing autotroph that reduces thiosulfate, nitrate, oxygen and can grow at temperatures up to 113°C. *Pyrodictium delaneyi* (Fig. 1(C)) reduces nitrate as well as ferrihydrite to the mineral magnetite. The *Desulfurococcaceae* have more genera than the *Pyrodictaceae* and generally have cooler optimal growth temperatures of 85–95°C. They grow mixotrophically or heterotrophically. *Desulfurococcus*, *Hyperthermus*, *Sulfophobococcus*, *Staphylothermus*, and *Thermosphaera* ferment sugars and peptides. *Stetteria*, *Thermodiscus* and some *Desulfurococcus* species use organic compounds to reduce elemental sulfur and generate hydrogen sulphide, organic acids, and alcohols. They are obligate anaerobes with the exception of *Aeropyrum pernix*, which is a microaerophile that respire oxygen. *Ignicoccus* species are strictly autotrophic elemental sulfur reducers that produce hydrogen sulphide. *Ignicoccus hospitalis* forms a stable co-culture with the archaeon *Nanoarchaeum equitans* that lives on the outer surface of *I. hospitalis*. *N. equitans*, in the *Nanoarchaeota*, has a genome size of 490 kb and a cell diameter of 350–500 nm. It lacks almost all known genes for lipid, cofactor, amino acid, and nucleotide biosynthesis and is completely dependent on *I. hospitalis* for survival.

Freshwater Generalists

Similar to the marine generalists, freshwater generalists are all archaea that belong to the *Thermoproteales* in the *Crenarchaeota* (Table 1). The *Thermoproteales* grow best at 75–100°C and consists of two families: the *Thermoproteaceae* and the *Thermofilaceae*. They can be distinguished from each other morphologically based on cell diameter since *Thermofilum*, the only genus in the *Thermofilaceae*, form very thin (0.15–0.35 µm diameter) filaments. The *Thermoproteales* differ from other (hyper)thermophilic archaea in that they are rod-shaped instead of coccoids. They also form a unique ‘golfclub’ morphology where a spherical structure forms at the terminal end of the rod during certain growth conditions. *Pyrobaculum* (Fig. 1(D)) are the only members of the *Thermoproteaceae* that grow above 100°C. They are facultative autotrophs capable of growth on many terminal electron acceptors such as elemental sulfur, thiosulfate, oxygen, nitrate, nitrite, selenate, selenite, arsenate, glutathione, Fe^{3+} -citrate, and ferrihydrite. In contrast, *Thermoproteus* are facultative autotrophs that only respire elemental sulfur. *Vulcanisaeta*, *Caldivirga*, and *Thermocladium* are obligate heterotrophs that reduce elemental sulfur, sulfate, and thiosulfate. *Caldivirga maquilingensis* and *Thermocladium modestius* are the only species in their genera, and both are also microaerophiles. Archaeal cell wall extract was shown to stimulate the growth of some *Thermofilum*, *T. modestius*, and *C. maquilingensis*, but the largest effect was observed on the growth of *Thermofilum pendens*. This latter organism is dependent upon the polar lipid extract of *Thermoproteus tenax* for growth.

Thermoacidophiles

Thermoacidophiles live in hot, acidic (pH <4) terrestrial environments. They are *Crenarchaeota* belonging to the *Acidilobales* and the *Sulfolobales* (Table 1). The *Acidilobales* consist of the genera *Acidilobus* and *Caldisphaera*. Both are obligate anaerobes and heterotrophs

that use sugars and peptides for growth, and secrete short-chain fatty acids. Their growth is stimulated by elemental sulfur that they use to produce hydrogen sulphide. *Acidilobus* live optimally at 80–85°C and pH 3.5–4.0, while *Caldisphaera* live optimally at 70–78°C and pH 3.5–4.5. The *Sulfolobales* are more metabolically versatile than the *Acidilobales* and have an optimum pH near 2.0. They are facultative autotrophs that oxidize elemental sulfur, thiosulfate, dithionite, Fe(II), metal sulphides, and hydrogen while reducing oxygen or sulfur when growing autotrophically. Most *Sulfolobus* and all *Metallosphaera* species are aerobic, *Acidianus* and *Sulfurisphaera* are facultative anaerobes, and *Stygiolobus* are anaerobic. *Stygiolobus* is the only obligate chemolithoautotroph and grows by hydrogen oxidation coupled with elemental sulfur reduction. *Acidianus* and *Sulfurisphaera* can both oxidize and reduce elemental sulfur. *Sulfolobus metallicus*, some *Acidianus* species, and *Metallosphaera sedula* can remove metals from metal sulphide minerals and have high resistance to metal toxicity.

Habitats

Marine Hydrothermal Vents

Marine hydrothermal vents are sites where seawater percolates through cracks and pores in the Earth's crust and reacts with hot subsurface rocks. The seawater is transformed into hydrothermal fluid as the seawater exchanges ions with the rock. Fluid-mineral reactions result in the loss of some dissolved chemical and volatile components (e.g., oxygen, sulfate) and gain in others (e.g., hydrogen, methane, carbon dioxide, sulphide, and reduced metals) at progressively higher temperatures as modified seawater migrates deeper into the crust. Hydrothermal venting is associated with mid-ocean spreading centers along tectonic plate boundaries, intra-plate volcanic hot spots, and back-arc basins and island-arc volcanoes in tectonic subduction zones. They are found in the deep-sea as well as in shallow coastal marine environments.

Deep-sea hydrothermal vents were first discovered in 1977 near the Galápagos Islands, and since then dozens of deep-sea hydrothermal vent fields in all the oceans have been discovered. The hydrothermal fluid emanating from these vents can reach temperatures over 400°C, which are kept in a liquid state due to the high hydrostatic pressure exerted on the fluids. These temperatures are too hot to support life, but hydrothermal fluids mix with cool seawater inside the crust and within metal sulphide mineral deposits on the seafloor and create cooler habitats that support thermophilic and hyperthermophilic life. These organisms use chemicals from both the hydrothermal fluid and the seawater for growth. However, the chemical composition of the fluids vary depending on the kinds of rocks that the seawater reacts with. If seawater reacts with ultramafic rock such as olivine from deep in the Earth's crust or with newly erupted magma in the shallow crust, then large concentrations of hydrogen are produced in the fluids. The hydrogen then supports the growth of thermophilic and hyperthermophilic autotrophs, particularly methanogens such as the *Methanococcales*. In contrast, along subduction zones where highly weathered seafloor that is millions of years old is melted and reacts with seawater, the hydrothermal fluids have low hydrogen concentrations but are rich in metals and highly acidic. In these cases as well as non-eruptive mid-ocean spreading centers, the thermophiles and hyperthermophiles found are autotrophs such as the *Aquificales* and the *Thermodesulfobacterales*. All deep-sea hydrothermal environments generally support the growth of heterotrophs such as the *Thermococcales* and marine generalists like the *Desulfurococcales* and the *Archaeoglobales*.

The discovery of life in environments lacking sunlight and oxygen profoundly changed the way in which scientists view the history of life on Earth and the likelihood of life beyond Earth. It was suggested that deep-sea hydrothermal vents may be where life first began on Earth. Indeed, there is evidence of ancient microbial life in hydrothermal vents from more than 3×10^9 years ago. This life may have been thermophilic and hyperthermophilic living inside the crust and existing solely on geothermally derived gases, sulfur compounds, and minerals. Furthermore, there is evidence for past hydrothermal activity on Mars and for currently volcanic activity in ice-covered oceans on some of the moons of Jupiter and Saturn. If life can exist in hydrothermal vents on Earth, then it is possible that extraterrestrial hydrothermal vents could support life beyond Earth in the same manner. Therefore, extraterrestrial hydrothermal vent sites are targets for space exploration and the search for life beyond our own planet.

Shallow marine hydrothermal vents are found at water depths of less than 200 m. These include the summits of seamounts and the flanks of volcanic islands. Because of the lack of hydrostatic pressure, the hydrothermal fluid temperatures are much lower. The highest measured temperature at shallow marine vent is 135°C just 22 m below sea level. Shallow hydrothermal vents are in the photic zone and thus are influenced by photosynthetic processes that occur near the surface and are often iron or sulfur dominated. Hydrothermal processes create geochemically distinct features such as metal sulphide-poor mineral deposits and focused brines. Directly above hydrothermal discharges, there is an increase in richness of heterotrophs belonging to the *Thermococcales* and the *Thermoproteales* and autotrophs belonging to the *Aquificales*.

Terrestrial Hot Springs

Hot springs are heated, low salinity (0.1%–0.5%) ecosystems associated with active volcanoes. They have pH values ranging from pH 0.5 to pH 9. Steam vents (i.e., fumaroles) at hot springs are features where water boils away before reaching the surface and have steam temperatures that range 150–500°C. Solfataras are steam vents that are rich in hydrogen sulphide gases and transport these gases to the surface. Hot springs provide many electron donors to the hyperthermophilic microbial communities such as hydrogen, sulphide, and ferrous iron and electron acceptors such as oxygen and elemental sulfur. Hot springs are found globally, but are particularly well known in Yellowstone National Park in the US; Hokkaido Island in Japan; Krýsuvík, Hveragerði, and Kerlingarfjöll in Iceland; the White Island in New Zealand; the Kamchatka Peninsula in Russia; and Pisciarelli Solfatara in Italy.

Research on thermophilic life in Yellowstone National park resulted in characterization of many new *Crenarchaeota* in the 1990s. Hydrogen metabolism is the major energy source in these springs, especially at higher temperatures. The hydrogen in the fluids is geothermally produced by the interaction of meteoric water with Fe(II). Oxygen and oxidized sulfur species are the major electron acceptors. Extensive studies at Yellowstone National Park have shown that hot springs have a range of geochemical gradients due to variations in pH, temperatures of diffusing fluids, and trace element and ammonia concentrations that provide a large biotope for different hyperthermophilic microbes as observed with the *Aquificales*-rich “filamentous-streamer” communities and *Sulfolobales*, *Desulfurococcales*, and *Thermoproteales*-rich “archaeal-dominated sediments”. Similar to hydrothermal vents, some of the earliest signs of life have been found in ancient hot spring deposits that are more than 3×10^9 years old.

Hot springs have a range of geochemical characteristics. Some fluids are oxygen-rich and have a $\text{pH} \leq 2$ and some fluids are anoxic, metal sulphide-rich and have a $\text{pH} 4\text{--}6$. Transition zones between them are often rich in elemental sulfur. The thermoacidophiles *Sulfolobus*, *Metallosphaera*, *Stygiolobus* and *Acidianus* are found in acidic, ferric iron- and oxygen-rich fluids whereas *Desulfurococcus*, *Thermoproteus*, *Pyrobaculum*, and *Thermofilum* are found in neutral pH fluids. In the Pisciarelli solfataria arsenate was shown to be an electron acceptor for *Pyrobaculum arsenaticum* in presence of thiosulfate and organic compounds. The Japanese coastal solfataric vents in Kodakara-Jima Island is where one of the first aerobic hyperthermophiles, *Aeropyrum pernix*, was isolated.

Marine Sediments and Hydrocarbon Reservoirs

It was estimated that 35% of all marine sediments are above 60°C suggesting that they provide a large habitat for thermophiles and hyperthermophiles. In these environments, buried organic material from the surface are likely to be the carbon and energy sources for the high temperature microbes that are present. This environment represents a new and largely unexplored habitat that may have an impact on the production and quality of natural gas and petroleum. Hyperthermophilic heterotrophs such as *Thermococcus* and *Pyrococcus* were the predominant microorganisms found at some depths in sediment cores collected offshore of New Zealand and Newfoundland, Canada. *Thermococcus* were also found in an uncontaminated oil reservoir in the Norwegian Sea, in a 90°C water-flooded oil well in China, and in Marcellus and Utica shale bed produced waters in western Pennsylvania. These organisms may be participating in the degradation of buried organics with concomitant hydrogen production. The organics and hydrogen present also support the growth of other thermophiles and hyperthermophiles such as hydrogenotrophic methanogens like *Methanothermococcus* and sulfate reducers like *Archaeoglobus*. The methanogens may enrich hydrocarbon reservoirs with biogenic methane making them more economically profitable while sulfate reducers can spoil a petroleum reservoir if too much sulphide is generated in the fluids. Preventing microbial oil spoilage can be accomplished by preventing the introduction of sulfate into the well or by the addition of inhibitory compounds such as nitrate. The upper temperature limit for life in hydrocarbon reservoirs is near 85°C .

Conclusion

The discovery and study of life that grows above 70°C have changed our perspective on life. We now have insight into how biological molecules such as proteins, DNA, and lipids can be thermostable at temperatures that normally denature these molecules. These organisms provide new enzymes and processes for industrial applications such as in vitro DNA replication using DNA polymerases from thermophiles and hyperthermophiles. They have also shown us unique adaptations to metabolic pathways such as the use of tungsten-containing enzymes and ADP-dependent kinases for glycolysis. High-temperature environments have shown us that life can exist entirely without sunlight and use chemicals provided from hot water-rock reactions. This has provided new ideas about life on the early Earth and the possibility of life on other planets and moons that once had or currently have hydrothermal fluid circulation below their surfaces. Future research will continue to identify and characterize novel thermophiles and hyperthermophiles, and will model and predict the impact of these organisms on the biogeochemistry of hot environments and their surroundings. These are becoming more relevant as we learn that hot environments are more widespread on the Earth than originally imagined. Hot environments can also be artificially created for industrial applications and the production of commercial enzymes and biofuels.

Extremophiles: Hypersaline Environments

Fernando Santos and Josefa Antón, University of Alicante, Alicante, Spain

© 2019 Elsevier Inc. All rights reserved.

Introduction

According to the definition of Oren (2015), hypersaline environments are those with salt concentrations more than twice that of seawater, and include solar salterns, salt lakes, saline soils and deep-sea brines, among others. Hypersaline systems are extreme environments and are thus inhabited by extremophilic organisms, namely halophiles or extreme halophiles. In a wide sense, halophilic organisms (or halophiles, “salt-loving” in Greek) are those that grow best in media containing from 1 to above 30% dissolved salts. Although there are no sharp limits between the different categories, halophiles can be classified as slightly halophilic (optimum growth between 1 and 4% salt; this category includes most marine microbes which cannot be considered as extremophiles), moderately halophilic (4%–15% salt), and extremely halophilic or hyperhalophilic (above 15% salt). Since most halophiles have an absolute requirement for sodium, some authors instead of “salt” refer to “NaCl” concentrations, using the same values.

The existence of extreme halophiles, among other extremophiles, was already acknowledged by Darwin in “The Voyage of the Beagle” in which he wrote “... Whether lakes of brine, or those subterranean ones hidden beneath volcanic mountains – warm mineral springs – the wide expanse and depths of the ocean – the upper regions of the atmosphere, and even the surface of perpetual snow – all support organic beings”.

Types of Hypersaline Environments

Hypersaline environments are widely distributed in the planet. In fact, around 50% of continental waters are hypersaline. In addition, there are terrestrial hypersaline environments such as soils (like that of the hyperarid Atacama Desert), salt crusts or sub-surface salt deposits. Despite their harsh conditions, most of these systems are inhabited by an active specialized microbiota. Hypersaline systems can be classified according to the origin of the salts (marine or thalassohaline and non-marine or athalassohaline) or to whether they are natural or artificial (for instance, salt lakes versus solar salterns). While coastal hypersaline systems are normally thalassohaline, inland salt lakes can either be thalassohaline or athalassohaline.

Salt lakes are hypersaline natural systems that, depending on the origin of their waters, their dynamics and the local climate conditions, may be exposed to sharp seasonal salinity changes. The Great Salt Lake in Utah and the Dead Sea are probable the first natural salt lakes ever studied and represent two very different systems: the first is thalassohaline and the second athalassohaline, with Mg^{2+} concentration so high as to inhibit the growth of even the most hyperhalophiles known. Soda lakes, with high salt and high pH (i.e., poly-extreme), are also among the first hypersaline systems studied and have been sources of a wealth of haloalkaliphilic microbes. During the last 10 years, the microbiota of more natural salt lakes has been characterized in detail. This is the case, for instance, of Lake Tyrrel in Australia (whose study allowed the formal discovery of a new archaeal phylum), the Tuz Lake in Turkey, Rumanian lakes such as Ursu and Ocnei, the $MgSO_4$ rich Hot Lake in Washington, the Aran-Bidgol lake in Iran, or the Siberian lake Novosibirsk.

Other high salt natural systems which are among the most extreme environments in the planet but still harbor microbial communities are the hypersaline Antarctic lakes, such as the Deep Lake, and the deep-sea hypersaline anoxic lakes (DHALs). Deep Lake constitutes a unique system in which water remains liquid at $-20^{\circ}C$ due to its high salt concentration (around 27%). DHALs are hypersaline basins located thousands of meters below the sea level, have salt concentrations 5–10 times higher than seawater, lack oxygen and light, and are exposed to high pressure. Since DHALs are denser than the overlaying seawater, there is an overlaying normally very stable pycnocline which can support a unique microbial community.

Finally, solar salterns used to concentrate salt by evaporation of seawater (or from hypersaline springs) represent the paradigmatic example of artificial solar hypersaline environments. Multi pond solar salterns consist of a series of interconnected shallow ponds with increasing salinity, from sea water to NaCl saturation. As the water gets pumped through the ponds, there is serial precipitation of salts and an increase of the total salinity. These changes in salinity are accompanied by a succession of different groups of microorganisms, from marine to extremely halophilic microbiota, each adapted to a salinity range. Thus, solar salterns can be used as a model to study how microbiota changes with salinity (Fig. 1), as discussed below.

Why is Salt Limiting Life and How do Microbes Cope With it?

Why are halophiles extremophiles or, in other words, why does salt limit growth? The first obvious answer is that salts “sequester” water and thus reduce the water available to biomolecules (water activity). In the case of cells, hyperosmotic media force the water to exit the cell which may collapse and suffer what is known as plasmolysis (the cell shrinks). In addition, although all solutes reduce

Fig. 1 Main changes in numbers and diversity of the microbiota along the salinity gradient from marine to NaCl saturation.

water activity, some, like MgCl_2 , can act as chaotropes, weakening electrostatic interactions and destabilizing biological molecules. Other solutes (like NaCl) are in fact kosmotropes that strengthen these interactions and stabilize macromolecules. Thus, life in some hypersaline environments is limited not only by water availability but also by the chaotropicity of their salts. Such is the case, for instance, of the Dead Sea or deep sea hypersaline anoxic brines, mentioned above.

To cope with osmotic stress, microorganisms in hypersaline environments have developed two types of strategies to retain the water inside the cells and avoid plasmolysis, namely the "salt-in" strategy and the accumulation of compatible solutes. Salt-in strategy consists of the accumulation of high concentrations of inorganic ions in the cytoplasm, mainly potassium. This strategy implies that all the intracellular machinery is adapted to function in the presence of molar concentrations of salt, which implies having acidic proteomes. On the other hand, compatible solutes are organic compounds compatible with the cell metabolisms that accumulate in the cytoplasm and counterbalance external osmotic pressure. These two strategies allow the maintenance of turgor pressure, cell volume, and the cytoplasmic ionic concentration and are therefore essential for survival and growth in hypersaline environments. As a general rule, most hyperhalophilic microbes (like extremely halophilic *Archaea* and some *Bacteria* belonging to the *Haloanaerobiales* and *Bacteroidetes* such as *Salinibacter*) use mainly the salt-in strategy while other extreme halophiles and most moderate halophiles accumulate compatible solutes. Examples of such substances are glycerol, derivatives of aminoacids such as ectoine, hydroxyectoine, and the universal compatible solute glycine betaine.

Since the solubility of oxygen in water decreases with salinity, aerobic respiration can be compromised at high salt concentrations. In addition, very often hypersaline environments are exposed to high solar radiation. Likely these are the reasons why many extremely halophilic microbes harbor retinal binding proteins (RBPs or rhodopsins) that can transform solar radiation into metabolically active ionic gradients. In fact, microbial retinal-based proton pumps (that can be considered as the simplest photosynthetic apparatus that transform light into a H^+ gradient which is coupled with ATP synthesis) were first discovered in extremely halophilic *Archaea*, although at that time had not been considered as such and thus the proton pump was named as "bacteriorhodopsin" ('bacterio' being a holdover from older, "pre-archaeal" taxonomy). Another adaptation for protection of the high solar radiation that many hypersaline systems experience is the high presence of carotenoids in its inhabitants from the three domains of life. These pigments are responsible for the pink-orange colors that hypersaline waters offer display. In the case of the bacterium *Salinibacter ruber*, a frequent inhabitant of these systems, the pigments can act as antenna of the retinal-binding proton pump xanthorhodopsin. This is highly unusual since antenna pigments are typical of other types of photosynthesis.

Microbiota of Hypersaline Environments: Solar Salterns as Models

Hypersaline environments are inhabited by organisms belonging to the three domains of life, although at very high salt concentrations (see Fig. 1) the system is dominated by extremely halophilic *Archaea* and *Bacteria* and a few (in numbers) representatives of the *Eukarya*, such as the phototrophic *Dunaliella* spp., some heterotrophic protists and fungi. Overall, the studies on microbiota

from different hypersaline environments show that salinity is one of the main drivers of microbial diversity in these systems, for the three domains of life. In this regard, it is useful to use the above-mentioned model of the solar salterns to classify the halophilic microbiota with respect to their salt requirements.

As a rule, as salinity increases from sea water to saturation (Fig. 1), overall prokaryotic diversity (at least at the phylum level, see Fig. 2(A)) decreases, *Archaea* numbers increase, and *Bacteria* and *Eukarya* numbers decrease. At salt concentrations from 20% to saturation, archaeal numbers are fairly stable while bacteria experience a sharp decrease (Fig. 3). In most close to saturation systems, mainly those from warm regions, total cell counts are in the order of 10^7 – 10^8 per milliliter (at least 10-fold over marine numbers) although there are examples of salt lakes and salterns with lower concentrations.

Overall, there is a transition along the salinity gradient from marine microbiota to a hyperhalophilic microbiota dominated by *Euryarchaeota* of the order *Halobacteriales* and frequently also members of the *Nanohaloarchaeota*. Very often, *Bacteria* of the *Bacteroidetes* group are also present as well as the green alga *Dunaliella*. In a wide sense, the range of different prokaryotic communities thriving at different salt concentrations can be divided into two groups: those living at salinities from seawater to 15% and the extreme halophiles inhabiting the 22%–37% salt range, with a mixed community in the intermediate range.

Fig. 2 Main prokaryotic groups present in (A) different ponds of Bras del Port solar salterns; (B) a collection of 50 brines and the overlying sediments from salterns around the world (in this panel, archaeal and bacterial values are referred to 100% independently).

Fig. 3 Changes in the Bacteria and Archaea in five ponds of increasing salinity (CM1, CM2, CCAB, CR30 and CR41) from Bras del Port solar salterns, Upper panel show changes in diversity and lower panel, changes in numbers.

The oxygenic phototrophic assemblage also changes along the gradient: diatoms and green algae, present at lower salinities, are substituted by cyanobacteria and, at highest salinities, the green alga *Dunaliella* is the only phototrophic primary producer. However, as mentioned above, a large part of the prokaryotic community is able to use solar light to obtain metabolic energy by means of RBP.

In the lower part of the salt range, Alpha-, Beta-, Gamma- and Epsilonproteobacteria, together with *Bacteroidetes*, *Actinobacteria* and *Cyanobacteria* are the main *Bacteria* while *Archaea* are represented by *Euryarchaeota*. As the salinity increases, the presence of all the bacterial groups except *Bacteroidetes* decreases. At very high salt, *Bacteroidetes* (frequently from the *Salinibacter* group) dominate. Interestingly, in medium-intermediate salt ponds, high GC *Actinobacteria* are substituted by low GC, from which there are no currently isolated representatives. Conversely, the archaeal assemblage is being progressively dominated by *Euryarchaeota* of the order *Halobacteriales* and *Nanohaloarchaeota*.

The microbiota of the sediments underlying crystallizer ponds, although with some specific characteristics (see Fig. 2(B)), presents some overlap with that of the overlying brines. Furthermore, members of the archaeal MBSL-1 candidate division have been detected in anoxic hypersaline sediments. This euryarchaeotal group, for which a methanogenic metabolism was hypothesized, had been only previously detected in DHALs of the Western Mediterranean, providing an example of how different types of hypersaline environments can harbor similar microorganisms.

Until recently, all extremely halophilic archaea were included within the phylum *Euryarchaeota*. However, in 2011, two groups almost simultaneously described the presence in solar salterns of what was lately named as *Nanohaloarchaeota*. In fact, sequences of this group had been detected years ago in the African lake Magadi although they remained unclassified. This again provides an example of database bias. This phylum is included within the archaeal superphylum DPANN, formed by phyla belonging to the so-called “microbial dark matter”, since no culture representative is available so far. Recently, many new groups have been included in the *Archaea* and *Bacteria* domains, such as the *Candidatus* Parcubacteria or the Woesearchaeota, which have also been detected in hypersaline environments. Their physiology, abundance and ecological relevance remain a mystery.

Very high salt systems, such as crystallizer ponds from solar salterns, are often dominated by the low GC euryarchaeon *Haloquadratum walsbyi* (the “square archaeon”), often comprising more than 60% of the archaeal assemblage. This organism has also been found in very high numbers in some solar lakes but there are other systems in which it is not relevant and can be outnumbered by other high GC euryarchaea like *Halorubrum* and *Halonotius* or other organisms.

One of the most intensely studied hypersaline systems are the multi pond coastal solar salterns Bras del Port, in Santa Pola (Spain), a widely documented example of how the description of natural microbial communities relies on the available techniques. In addition, these systems provide examples of how culture-independent techniques can guide the isolation of ecologically relevant microbes. The case of the gammaproteobacterium *Spiribacter* can be considered paradigmatic. This previously unknown bacterium was first detected as an abundant component of the community in a metagenomic dataset from a 13‰ pond. The genome assembled from the environment provided clues on how to culture this bacterium that was isolated shortly after. Before the description of this genus, bacteria readily isolated but present only at very low numbers in low-medium salinity ponds were taken as models for moderate halophiles.

Although the eukaryote assemblage along hypersaline systems has been way less studied than prokaryotes, high throughput 18S rRNA gene analysis has identified four salinity classes selecting for four different protistan communities: 4%–9‰, 14%–24‰, 27%–36‰ and 38%–44‰. Overall, protistan diversity is remarkable, especially in the 14%–24‰ range, although the information regarding abundance is still scarce. In fact, some studies based solely on microscopy failed to detect protists at salinities above 30‰. In the same way, the role that protistan bacterivory plays in controlling prokaryotic communities at very high salt concentrations is still an open question. It seems clear, however, that bacterivory decreases at very high salt, leaving viruses as the main biological factor controlling prokaryotic numbers.

Although close to saturation hypersaline systems were once considered steady-state systems and the same types of hyperhalophilic microbes were expected to be found all over the world, recent studies indicate that there are dynamic microbial successions in these systems, both for prokaryotes (Fig. 3) and eukaryotes. Furthermore, not all the high salt systems around the world are inhabited by the same microbial groups. Therefore, caution must be exerted when drawing general conclusions even for these “simple” environments.

Viral Communities in Hypersaline Environments

One of the most striking characteristics of close-to-saturation hypersaline environments is that they harbor the highest concentrations of virus-like particles (VLPs) reported so far for aquatic systems. These values range from 10^7 to 10^{10} VLPs/ml (Fig. 4). In multi-pond solar salterns there is a clear correlation between the salinity of each pond and its viral concentration. One could think that this increase in VLPs is due to the concentration of viruses present in previous ponds although metagenomic studies indicated that this is not the case, since each pond harbors a specific viral community. As with the host microbiota, viruses in the most hypersaline systems share some traits that differentiate them from the communities inhabiting at medium and high salt. In other words, there is a “hypersaline-ness” of the viral communities in very high salt systems, as there is a “marine-ness” of marine viral communities.

Fig. 4 Virus like particles (VLPs) concentrations and virus to cell ratios measured in different solar salterns and salt lakes around the world.

First Principles of Clinical Microbiology: Collection, Handling, and Diagnostics

Michael A Bachman and William D LeBar, University of Michigan, Ann Arbor, MI, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction to Clinical Microbiology

Clinical microbiology focuses on the isolation and characterization of infectious organisms so they can be managed and treated in patients. Infections can be caused by bacteria, fungi, viruses, and parasites. To diagnose an infection, a sample must be collected from a patient at a body site where the detection of a pathogen or its associated biomarkers is likely to signify disease. The specimen must be transported to the laboratory in a manner that preserves the specimen for the intended testing. Then the specimen must be tested in a way that is sensitive and specific for the suspected organism causing the disease. Finally, these results must be communicated back to a clinician in a way that he or she can interpret and act on appropriately.

Clinical microbiology is arguably the first discipline of personalized medicine. As an example, a patient has the signs and symptoms of a urinary tract infection, including increased urgency, frequency, and pain with urination. A urine sample is collected and cultured quantitatively. Within 24 h, the clinical microbiology laboratory reports the species and quantity of bacteria found in the urine. 1–2 days later, the laboratory reports the susceptibility of that patient's bacterial isolate to a panel of antibiotics approved to treat urinary tract infections. The patient's clinician can then choose an antibiotic that is predicted to be effective against that patient's infection.

A pioneering microbiologist, Robert Koch, established the paradigm of clinical microbiology that is still in practice today. In proving that the bacterium *Bacillus anthracis* caused the disease anthrax, he developed what have become known as Koch's postulates which are: (1) the microorganism must be observed in all cases of the disease, (2) the microorganism must be isolated and grown in pure culture, (3) microorganisms from the pure culture, when inoculated into a susceptible animal, must reproduce the disease, (4) the microorganism must be observed in and recovered from the experimentally diseased animal. Many pathogens have been linked to disease by fulfilling these postulates. For these pathogens, clinical microbiology labs can diagnose infections in patients with compatible signs and symptoms by isolating the microorganism in pure culture, or detecting it by an alternative method. When Koch's postulates have not been met, interpretation of detection of the microorganism in a patient can be challenging or impossible.

Colonization and Infection

The primary goal of the clinical microbiology laboratory is to aid in the diagnosis of infections. However, many pathogens can live on or in a body site without causing signs and symptoms of disease. For bacteria, fungi, and parasites this is termed colonization, and establishes a normal flora of microbes in certain body sites. For viruses, an analogous process is latent infection, where the virus or viral genes persist within cells for long periods of time. Detecting colonization or latent viral infection can mislead a physician by incorrectly implicating the wrong microbe to explain a patient's medical condition. To accurately diagnose infections, the clinical microbiologist must have knowledge of the normal flora of various body sites. For example, *Streptococcus pneumoniae* is a frequent colonizer of the nasopharynx, particularly in young children. However, it can also cause meningitis and bloodstream infections. Isolation of *S. pneumoniae* from either the CSF or blood is compelling evidence that it is causing an infection whereas isolation from the throat is not. *S. pneumoniae* also causes pneumonia, but diagnosis can be challenging since the site of colonization is near the site of infection and may be sampled inadvertently. Therefore, diagnosis of pneumonia requires careful processes to ensure that the lungs, and not the upper respiratory tract, have been cultured.

Viral infections require integration of time and body location into diagnosis. Cytomegalovirus infects 40%–50% of people in the United States and approaches 100% in some countries (Specter, 2009). When it first infects someone, it may produce signs and symptoms of an infection. Once it establishes a latent infection within cells, it can persist for years or a lifetime without causing further symptoms. CMV can also reactivate from a latent infection to cause disease. Finally, some viruses cause an acute infection but are eventually cleared by the immune system. But the infection may trigger an immune response that can be measured as antibodies against the virus. If detection of antibodies (serology) is used as part of the diagnosis, then past infection must be distinguished from current infection, and latent infection must be distinguished from primary infection or reactivation.

For many infections, colonization of one body site is a prerequisite for infection of another. This is particularly important for antibiotic-resistant bacteria, for which infections are difficult to treat. For example, colonization of the intestinal tract with vancomycin-resistant enterococci (VRE) is concerning because that patient may subsequently become infected or could spread that bacteria to another patient in the hospital. Therefore, clinical microbiology laboratories now also seek to identify patients colonized with microbes that could later cause significant infections.

Detection, Quantification and Characterization

At a minimum, diagnosis of infection requires detection of the pathogen or a pathogen-specific host response. Detection can be through targeted or non-targeted approaches. The enduring non-targeted approach, as pioneered by Koch, is culture. A specimen is introduced onto nutrient-containing media in either agar or a broth. The breadth of organisms that can grow on the media is limited only by the nutrients supplied and the time, temperature and atmospheric conditions of incubation.

Different combinations of media can be used to aid in detection and identification of suspected pathogens from a particular body site. Sheep blood agar supports growth of many, but not all, types of bacteria. Sheep blood agar can also differentiate bacteria for preliminary identification, as groups including *Staphylococci* and *Streptococci* hemolyze the blood creating clearings around their colonies. Media additives, such as antibiotics or other chemicals, can be used to select for certain organisms and aid in their rapid identification. MacConkey agar is selective for enteric bacteria such as *Escherichia coli* and *Salmonella* because it contains crystal violet and bile salts that are inhibitory to many other bacteria and differential because it contains lactose (Atlas, 2015). Most *E. coli* ferment lactose, reducing the pH of the media and causing the neutral red indicator to turn pink. *Salmonella* can grow in bile salts but doesn't ferment lactose and has clear colonies. The combination of sheep blood agar and MacConkey allows growth of many bacteria and can also aid in rapid diagnosis once a colony grows.

Targeted approaches to diagnosis include detection of molecules produced by the pathogen (antigens), pathogen-specific immune responses (antibodies or cell-mediated immunity), and RNA or DNA specific to the pathogen (molecular diagnostics). With these approaches, the timing of infection must be accounted for because they do not necessarily distinguish between viable and nonviable organisms. Antigens and nucleic acid may persist in the body for surprisingly long periods after clearance of viable pathogen. Pathogen-specific antibodies may last for the lifetime of the patient. In combination with direct detection of the organisms, these approaches can distinguish current from past infection, and primary, latent, and reactivation infections.

In addition to detection, diagnosis may also require quantification. Most diagnostic approaches in clinical microbiology focus on the detection of a pathogen that, when found in that body site indicates infection. But as mentioned above, colonization and latent infections can confound interpretation of simply detecting a bacteria or virus. Quantification is one method to improve the specificity of testing. For bacteria, quantification can aid in diagnosis of infections near sites of colonization, such as urinary tract infections. For viral infections, quantification is valuable in distinguishing latent infection from primary infection or reactivation. Latent infection by CMV can cause shedding of virus from mucosal surfaces and into the blood. Detection of a low level of CMV in the blood, along with the presence of CMV-specific antibodies would be consistent with latent infection. But higher levels in the blood, and an increase over time, indicate reactivation of the infection.

Characterization of a detected microbe is needed to determine its significance. Typically, identification to the species level is required to assess the likelihood of causing the infection and the prognosis. However, not all strains within a species may be pathogenic. Some strains have genes that enable virulence, the ability to cause disease, whereas other strains are avirulent. This variation is striking for *E. coli*, where some isolates colonize our intestines harmlessly, while others cause urinary tract infections, diarrhea, meningitis, and bloodstream infections. In recognition of these differences, Stanley Falkow created Molecular Koch's postulates to identify the genes that enabled virulence of certain isolates within a species (Falkow, 1988). This concept has begun to enter the clinical microbiology laboratory in the form of directed molecular tests. For example, diarrhea-causing strains of *E. coli* can be detected based on their gene content among the billions of bacteria and potential bystander *E. coli* in a stool sample from a patient. In other cases, antibiotic resistance is a primary concern in diagnosing both infection and colonization. From the intestinal tract, detection of VRE can be used to implement precautions to prevent spread to other patients, whereas detection of susceptible *Enterococcus* has little medical significance. Detection of VRE in the blood typically requires a rapid change in treatment to make sure an effective antibiotic is used.

Pre-Analytic, Analytic, and Post-Analytic Phases of Testing

Clinical microbiology testing, like all clinical laboratory testing, has three phases: pre-analytic, analytic, and post-analytic (Table 1). All phases are critical to making the correct diagnosis, and errors in any of them can lead to incorrect results and poor outcomes for the patient. The pre-analytic phase is all steps that take place before the samples are analyzed (Lifshitz, 2017). This includes assessing the need for the test, placing an order, determining the site for collection and collecting the sample, identifying the sample properly, transporting the specimen to the lab, and preparing the sample for analysis (Table 2). The analytic phase of testing includes inoculation and incubation of the specimen, detection, quantification, and characterization of pathogens, and recording test results (Table 3). The post-analytic phase includes the reporting of the test result, the clinician accessing the report and then interpreting the result, integrating it with other clinical data and acting on the result in the care of the patient (Table 4).

Table 1 Laboratory considerations for patients with suspected infection

<i>Pre-analytic considerations</i>	<i>Analytic considerations</i>	<i>Post-analytic considerations</i>
Differential diagnosis	Processing triage	Result interpretation
Test ordering	Assessment of specimen quality	Action taken
Specimen collection	Rejection criteria	
Specimen transport	Media selection	
Selection of transport device	Appropriate incubation	
	Examination/enumeration	
	Result reporting	

Table 2 Variables in pre-analytical phase of microbiology testing

<i>Differential diagnosis</i>	<i>Test ordering</i>	<i>Specimen type</i>	<i>Specimen collection</i>	<i>Specimen transport</i>
Bacteria	Culture	Body fluid	Timing relative to infection	Selection of transport device
Fungi	Molecular	Tissue	Cleaning of site	Temperature
Virus	Antigen	Swab	Method and equipment	Preserved vs. unpreserved
Parasite	Antibody	Foreign object		

Clinical microbiology laboratory acts as a consultant.

Table 3 Variables in analytic phase of microbiology testing

<i>Processing triage</i>	<i>Assessment of specimen quality</i>	<i>Rejection criteria</i>	<i>Media selection</i>	<i>Appropriate incubation</i>	<i>Examination/enumeration</i>	<i>Result reporting</i>
Centrifugation	Microscopy	Inadequate volume	Adequate nutrients	Temperature	Detection	Detected/not detected
Decontamination	Visual inspection	Improper temperature	Selective for suspected pathogen	Percent carbon dioxide	Quantification (culture, molecular)	Quantification
Homogenization	Measurement of volume	Contamination or incorrect body site	Differentiates pathogens	Oxygen/reducing capacity (anaerobic organisms)	Characterization (species identification, antibiotic resistance, virulence genes)	Characterization of pathogen, including interpretation of antimicrobial susceptibility testing (if applicable)
Separation	Indicators of oxygen exposure				Flora, contamination, or pathogen	Comments on flora or contamination

Clinical laboratory assumes responsibility for testing.

Table 4 Variables in post-analytic phase of microbiology testing

<i>Result interpretation</i>	<i>Action taken</i>
Is this result consistent with the signs, symptoms, and other clinical data from the patient? Is there an alternative explanation?	Supportive care
Does this represent colonization, active infection, latent infection, past infection, or contamination?	Addition or alteration of prescribed antimicrobials
Does the infection need to be treated?	Additional diagnostic testing

Clinical laboratory provides education on result interpretation and acts as a consultant.

Although errors can occur at any stage of testing, the majority of testing errors occur in the pre-analytic phase. In this phase, the microbiology laboratory consults on which tests to order to diagnose a suspected infection, what type of specimen to collect, and how to transport the specimen. The clinical microbiology lab assumes direct responsibility for the testing towards the end of the pre-analytical phase when the specimen is received in the lab and is responsible throughout the analytic phase until the result is reported in the patient's medical record. In the post-analytic phase, the laboratory can educate the clinicians on how to interpret the result.

Specimen Collection

Proper specimen collection in the pre-analytic phase is essential to diagnose infections. This responsibility rests with the ordering clinician, who makes the choice of specimen site and collection technique. Based on the patient presentation, the clinician must make a list of pathogens that may be causing the patient's disease. Next, the clinician needs to decide on the best specimen to make the diagnosis. In general, there are four types of specimens for microbiology: tissue, body fluids, swabs, and foreign objects. Often the decision of specimen type is straightforward. If suspecting a bloodstream infection, the clinician should collect a sample of the patient's blood. However, sometimes the choice of specimen is more complex. If suspecting pneumonia caused by *Legionella pneumophila* or *S. pneumoniae*, the first specimen collected may be urine to detect a pathogen-specific antigen since this approach is rapid, relatively inexpensive, and usually non-invasive for the patient. Collecting multiple specimens consecutively or concurrently can increase the chances of making the diagnosis. For either of these organisms, the clinician may also collect a lower respiratory specimen for detection by culture or molecular methods, and a blood culture may detect *S. pneumoniae* in a patient with pneumonia.

In addition to collecting from the most informative site, the amount of specimen collected determines the chances of detecting the pathogen. With few exceptions, more specimen is better. In the case of diagnosing a bloodstream infection, the standard of care is to collect multiple specimens over time and with relatively large volumes (16–20 mL for an adult). This is because, despite the dramatic symptoms and deadly outcomes of bacteremia, the numbers of circulating bacteria (colony forming units, or cfu) can be less than 5 per mL. For other body fluids, again more is better and the laboratory can concentrate the specimen if needed. If the pathogen is suspected to be infecting body tissue, then as large a specimen as is safe and feasible should be collected. A saying in clinical microbiology is “Give me a liter or a lobe” (Paxton, 2004).

The method of specimen collection significantly impacts both the likelihood of detecting the pathogen. Swabs are a common method of collecting specimens for microbiology testing, but are only useful to diagnose certain infections. They are ideal for diagnosis of upper respiratory and urogenital infections, where vigorous sampling can collect infected epithelial cells and exudate. Swabs are less useful for diagnosing infections of tissue since they are only sampling the surface of the infected site. A biopsy of the specimen is almost always superior (Baron et al., 2013).

Collection technique is critical to avoid contamination with members of the body's colonizing bacteria, or microbiota. For bloodstream infections, the skin overlying the sampled must be cleaned rigorously, and the rates of contamination by skin bacteria are a standard measure of quality of care in a hospital. Similarly, urine must be collected in a way that minimizes contamination by bacteria colonizing the urethra and surrounding skin. Sampling the lung either requires protecting the sampling instrument on its way through the throat, or demonstrating that the sample is from the lower respiratory tract based on the type of human cells present in the specimen.

Timing of specimen collection is also important for both correct interpretation of results and maximizing chances of recovering the pathogen. The *Plasmodium* parasites that cause malaria periodically lyse out of red blood cells causing the symptom of fever. Therefore, collecting a specimen before a fever increases the chance that they will be detected within red blood cells by microscopy. Culture-based methods rely on a specimen with viable organisms, so at least one specimen should be collected prior to giving antibiotics. The timing of specimen collection relative to the suspected onset of infection is also important. If collected early, the pathogen may not have replicated sufficiently to be detectable in the specimen. If collected late, its density may be waning. Pathogen-specific host responses develop over time and the timing of specimen collection can determine if a response is detected, and if that response indicates past or current infection.

Specimen Transport

Once a specimen is collected, it must be transported to the laboratory in a manner that preserves the viability of the pathogen or the analyte that will be detected. For culture-based testing, preserving viability is paramount. Transport is usually at room temperature, but can differ with the type of microbe suspected (Leber, 2016). Swabs are often inserted into a tube with liquid media for transport, and separate transport devices are available for bacteria and viruses to preserve their viability. Bacteria with anaerobic metabolism may be killed by exposure to oxygen. Large pieces of tissue and volumes of fluid preserve viability and anaerobic conditions for short periods, reinforcing the hyperbole of “Give me a liter or a lobe.” Smaller samples should be placed in specialized transport tubes that maintain anaerobic conditions and have color (E_h) indicators to determine if oxygen has contaminated the specimen. Swabs are generally a poor choice for anaerobic cultures because they sample the surface of the infection and not the infection itself, but swab transport media are effective at maintaining viability of any anaerobes recovered. Blood culture bottles serve as both the transport and culture vessel. For molecular diagnostic tests, transport tubes may have additives that preserve DNA and RNA but not the pathogen itself. For each test that can be ordered, clinical microbiology laboratories publish handbooks stating what body site of specimen to sample, what volume is suggested, the minimum required volume, the type of tube or container to be used, the temperature for transport, and how quickly the sample must reach the laboratory.

Specimen Processing

Once the specimen reaches the laboratory, usually it must be processed before it can be tested. Specimen processing involves concentration, decontamination, homogenization, separation, or a combination of these processes. These choices are made based

on a combination of what the clinician ordered and established policies in the laboratory, shifting responsibility for the specimen from the clinician to the laboratory.

Large volumes of fluid can be concentrated by centrifugation, pelleting the pathogen and human cells at the bottom of the tube. Although receiving more specimen is better, there are limits on the volume that can be added to a culture plate or tested in an instrument. The supernatant is removed and this pellet, potentially enriched in pathogens, can be tested further.

Decontamination is important to detect slow growing pathogens like *Mycobacteria* and *Legionella*, where small numbers of contaminating bacteria can overgrow the pathogen of interest. This can obscure the detection of these organisms in broth and agar cultures. Decontamination techniques use harsh chemical treatments, such as sodium hydroxide, that *Mycobacteria* can withstand more readily than other types of bacteria and acid shock that enriches for *Legionella*. This is a balancing act, and laboratories aim for low but detectable rates of contamination to indicate that the process was not so harsh as to also kill the suspected bacterium.

In a specimen with multiple anatomic parts or fluid phases, the choice is to combine through homogenization or separate. Tissues can be homogenized by sterile, mechanical processes such as tissue grinders and Stomachers, combining specimen with saline or culture media to release pathogens for detection. In contrast, blood can be tested whole, or separated into serum or plasma components. The type of blood transport tube determines the blood compartment that is tested, so the clinician must again decide where to look for the pathogen to maximize chances of detection.

To process a specimen properly, the technician must predict if the specimen contains one or multiple bacteria. This can determine if testing should be done in a liquid form or on agar. In specimens such as blood and sterile body fluids, there is usually only one pathogen, so the specimen can be tested as a homogeneous liquid by culture or other means. Other specimens will have multiple microbes present, either because they are part of a polymicrobial infection, or the pathogen and some colonizing microbes may be present. These specimens should be processed in a way that enables detection of each microbe separately. Through culture, this means inoculating the sample on selective and differential agar so colonies of each bacterium can be visualized and analyzed separately. For molecular methods, the test must detect multiple microbes as well as it detects single pathogens. Often if one pathogen is predominant, it can consume reagents in a molecular test, analogous to contaminating bacteria overgrowing mycobacteria in culture. To interpret mixed cultures, quantification can be helpful, but this must be anticipated at the time of specimen processing. Quantitative cultures on solid media, using a defined inoculum, can distinguish infection from colonization as discussed above for urine cultures. Even if the volume of sample cultured was not precisely measured, relative quantitation can be done to indicate that one pathogen is predominant in the sample.

Specimen Testing

Testing methodologies each have their own benefits and drawbacks relative to the pathogen being sought. Direct microscopy of a specimen provides a rapid and inexpensive way to detect pathogens. In addition to the Gram stain for bacteria, specific stains for fungi, mycobacteria, and blood parasites are routinely performed. The Gram stain also allows evaluation of human somatic cell types present in the specimen as a measure of specimen adequacy and risk of contamination from colonized body sites. The sensitivity of direct microscopy depends on the volume of sample used and the ability of the stain to highlight the organism. Fluorescent stains can increase the sensitivity of microscopy, and are used routinely to detect fungi and mycobacteria.

Antigen detection is of primary utility in non-invasive investigation of infections that infect deep tissues or fluids. The specimens tested are typically blood or urine that can be readily obtained from a patient. These approaches are particularly useful for fungal infections, where culture is slow and may require invasive procedures to sample the lungs or other sites of infection. Antigen detection may also be helpful in stool to diagnose parasitic infections. The main challenge with these approaches is cross-reactivity with other antigens found in these body fluids or other pathogens that cause a similar disease presentation.

The utility of antibody detection (serology) varies widely and is specific for each pathogen. In general, serology is used when other direct approaches of detection do not perform well. For fastidious bacteria and fungi, serology may be the only reliable method to determine if a patient has been infected. In other infections, the pathogen is present at very low concentrations or only transiently, making direct detection difficult. Furthermore, the patient may present with symptoms as the pathogen burden wanes. For example, encephalitis from arboviruses (e.g., west Nile virus) is most effectively diagnosed by serology from cerebrospinal fluid as opposed to viral detection. Serology is one of the few diagnostic methods that can provide information about time of infection, but the interpretation is specific to each pathogen. The clinician must have a basic understanding of the immune response to the suspected infection to know how long it takes to mount an initial IgM antibody response, when an IgG response may emerge, and how long each of them persist.

The strengths and drawbacks of culture are implicit in the fact that it requires growth of the organism of interest. The strengths are that it is a largely unbiased approach that may identify rare organisms causing a disease. It is also inexpensive. The main drawback is that culture is only as fast as the organism's growth rate and requires hours to days. It is also limited by which organisms the culture media can support for growth. Culture is a largely manual method, but the development of automated systems for specimen processing, incubation, and monitoring of growth is likely to speed up time to diagnosis and further reduce costs through decreased personnel time.

Current molecular detection methods are targeted to one or a set of pathogens of interest. These can be performed directly from a specimen or used for pathogen identification after culture. Molecular assays can either give a qualitative result of present or absent, or quantify the pathogen relative to the volume of sample. The benefits of molecular methods are exquisite sensitivity and specificity and precise quantification of pathogens. The main drawbacks are their directed nature and high cost. Unbiased sequencing

techniques, that identify nucleic acids directly from samples, are an intriguing approach to rapidly identify and perhaps quantify specimens in patient samples. Although not currently in wide use, these approaches have the potential to disrupt and revolutionize clinical microbiology.

Antimicrobial Susceptibility Testing

Once a pathogen has been detected, antimicrobial susceptibility testing is a key part of clinical microbiology testing. A few pathogens have predictable susceptibility or resistance to certain antibiotics, so further testing is unnecessary. But for pathogens where isolates vary in their ability to resist an antibiotic, antimicrobial susceptibility testing is critical to guide effective treatment of the infection. Bacteria, yeast, and mycobacteria are routinely tested for susceptibility in clinical laboratories. Anaerobic bacteria, molds, and viruses are more difficult to test, so susceptibility testing is usually performed in specialized reference laboratories or in response to treatment failures.

The goal of antimicrobial susceptibility testing is to predict if an infection with the detected pathogen can be treated with normally achievable antibiotic concentrations at the site of the infection. In most cases this is done through phenotypic testing. Varying concentrations of an antibiotic are added to a culture of the pathogen isolated from the patient, and the minimum concentration of antibiotic that inhibits growth is recorded (Minimum Inhibitory Concentration, MIC). This result is interpreted as the isolate being susceptible or resistant to the antibiotic based on what is known about patterns of resistance within the microbial species and pharmacokinetics and pharmacodynamics of the antibiotic in patients.

Genetics of the microbe often determines if it is susceptible or resistant to an antibiotic, so genotypic testing can also be useful. When the mechanistic relationship between a gene and resistance to an antibiotic is robust and predictable, molecular tests with their exquisite sensitivity and specificity can produce rapid and reliable results. However, the genetic diversity of microbes is such that many mutations or genes could lead to resistance against the same antibiotic. In these cases, phenotypic testing is more useful than genotypic testing. Again, as molecular techniques move towards unbiased approaches, rapid detection of multiple genotypes that yield the same phenotype may be possible.

Concluding Remarks

Clinical microbiology is focused on the detection, characterization, and quantification of pathogens from patient samples to enable the diagnosis, treatment, and management of infections. Clinical microbiologists must be experts in all aspects of pre-analytic, analytic, and post-analytic phases of microbiology testing. We must educate clinicians on the critical aspects of test selection, specimen collection and transport, and result interpretation that occurs outside the laboratory. We must also ensure excellent quality of testing within the laboratory, from the time when the laboratory receives the sample until the result is posted. This requires a combination of biological knowledge of how and where microbes colonize, remain latent, and cause symptomatic disease as well as an understanding of the analytical principles, strengths and drawbacks of each testing modality. As new technologies are introduced to the field, clinical microbiologists will be able to diagnose infections more rapidly and precisely than ever before.

Glossary

Amplicon A piece of DNA resulting in an amplification process.

Antibody Glycoprotein (immunoglobulin) molecule developed by the body in response to, and interacting specifically with, an antigen, as part of the body's immune response.

Antigen A foreign substance that induces the formation of antibodies in the body that react to that substance, specifically.

Bacteriophage A virus that infects bacteria; often called a phage.

Bacterium A prokaryotic, microscopic, one-cell microorganism found as a free-living organism/parasite, which multiplies by binary fission.

Base pairs (bp) Formed by hydrogen bonds between purine and pyrimidine nitrogenous bases on opposite strands of DNA or RNA. Abbreviated bp, the length of a particular genome is usually measured and reported in bp.

DNA polymerase The enzyme that synthesizes or builds DNA from a DNA template using nucleic acids. The intact enzyme purified from bacteria has the ability to synthesize and edit DNA sequence. The editing function comes from nuclease activity.

Endotoxin A heat-stable lipopolysaccharide that is found in the outer membrane of Gram-negative bacterial cells. The toxin is released from the cells when lysis occurs.

Enterotoxin A toxin released from several types of bacteria in the intestines that specifically affects the host's intestinal mucosal cells, which causes vomiting and diarrhea.

Exonuclease An enzyme that digests or degrades nucleic acids starting from the 5' or 3' terminus and extending inward.

Expression To 'express' a gene (DNA or RNA sequence) is to cause it to work. A gene that encodes a protein will be transcribed and translated, when expressed, to produce a specific protein.

Gene library A genomic library is a mixture of thousands of different clones containing a vector (e.g., derived from bacterial plasmid, or phage) carrying an insert, the cloned DNA.

Immunoassays It is a serological technique that measures the presence or concentration of analyte (antigen) with the help of homologous antibody.

Internal control Nontarget analyte added to the test reaction to judge performance and validity of a particular test. This material should generate a positive result when testing conditions are optimal.

Klenow fragment A genetically modified version of bacterial DNA polymerase that has the polymerase function still active, but the polymerase 5' → 3' exonuclease activity has been removed.

Midvariant RNA sequence A 220-nucleotide-long sequence that is recognized by Q-beta replicase enzyme. The enzyme binds to the sequence and starts amplification.

Multiplex PCR The amplification of multiple targets by different PCR primers within the same reaction tube.

Neurotoxin A toxin released from bacteria that damages, destroys, or impairs the functioning of nerve tissues.

Polymerase chain reaction A molecular technique for synthesizing a specific sequence of DNA *in vitro*, even in the presence of excess nonspecific DNA. Primers (short DNA oligonucleotides) are added in the presence of nucleotides and Taq polymerase. When the temperature is changed, the target DNA sequence is repetitively denatured and copied. PCR can amplify sequences after converting the RNA to DNA using reverse transcriptase. This is called 'RT-PCR'.

Primer A small oligonucleotide (anywhere from 6 to 50 nucleotides long, sometimes longer) used to bind and prime DNA synthesis. A primer that binds to the DNA template is used to start the replication. Primers are important for DNA sequencing and PCR.

Restriction endonucleases These enzymes are among the most useful in recombinant DNA technology, capable of introducing a single cleavage site into a nucleic acid. The site of cleavage depends on the sequence; recognition sites contain from 4 to 10 specific nucleotides. The produced digested ends of the nucleic acid chain may either be blunt or contain a 5' or 3' overhang ranging from one to eight nucleotides.

Sensitivity The ability (probability) that a particular test will give a positive result when the test sample is positive for the targeted analyte (i.e., no false negatives).

Shotgun cloning It is a method used to amplify genomic DNA by cloning small DNA pieces generated by a cut using a restriction enzyme or a physical method. These DNA fragments are cloned into a vector (plasmid).

Single nucleotide polymorphism (SNP) A genetic variation resulting from a single nucleotide difference in the genome of a species. These differences can be exploited, for example, to discriminate strains of bacteria. This discrimination may help with determining a pathogenic from nonpathogenic strain or aid in tracing the source of an outbreak of illness.

Specificity The likelihood (probability) that a particular test will produce a negative result when only nontarget analytes are present (i.e., no false positives).

This article is a reprint of S.F. Al-Khaldi, J. Kase, A.K. Singh, S. Sharma, Foodborne Pathogen Detection, Using Rapid Technologies, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

Worldwide there are at least 200 different diseases known to be associated with bacterial or viral contamination of food related to bacterial and viral infections that are known to be transmitted by food. A recent study by the US Centers for Disease Control and Prevention found that 31 pathogens caused 9.4 million foodborne illnesses, 55 961 hospitalizations, and 1351 deaths. However, an additional 38.4 million illnesses, 71 878 hospitalizations, 1686 deaths were found to be related to unspecified food-related agents, suggesting that we have only begun to understand the scope of the problem (Scallan et al., 2011). We must not only use all the research tools at our disposal but also develop new technologies for identifying bacteria and adapt those tools for efficient use in clinical microbiology laboratories, farms, and food production areas. Molecular methods can play an important role in facilitating rapid and specific detection of pathogens on the farm before the food enters a global distribution network and in the clinical microbiology laboratory after occurrences of foodborne infection or poisoning in patients. Molecular methods can work as screening and qualitative (absence/presence) tools as well as quantitative measurements.

Although this article focuses on newer molecular and immunological methods, classical microbiology methods (not addressed in this article) are still important. Regulatory agencies such as the US Food and Drug Administration and the US Department of Agriculture require traditional isolation and culturing of foodborne pathogenic bacteria to verify contamination. Many of those methods rely upon the ability to first obtain an isolated organism.

Conventional Polymerase Chain Reactions

As with most technological advancements, there was a beginning that laid much of the necessary groundwork. In the case of modern molecular biology, the starting point is described in the 1953 paper published by James Watson and Francis Crick in the journal *Nature* (Watson and Crick, 1953a,b). In the article presenting a proposed structure for deoxyribonucleic acid (DNA), they state, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material."

About 20 years after the publication of the Watson and Crick paper, the conceptualization of a DNA copying process was initiated (Kleppe et al., 1971) and later demonstrated (Saiki et al., 1985), leading to the invention of polymerase chain reaction (PCR), largely attributed to Dr Kary Mullis in 1983 while employed by the Cetus Corporation (Mullis et al., 1986). Six components are essential to the performance of PCR: the target DNA template; the deoxyribonucleotides (dNTPs) consisting of a nitrogenous base (adenine, guanine, thymine, or cytosine – usually abbreviated A, G, T, or C, respectively), a deoxyribose sugar, and a phosphate group; a DNA polymerase, the enzymatic driver that catalyzes copying of genetic material; a buffer to maintain a desired pH level; divalent cations (usually added as $MgCl_2$) needed for DNA polymerase function; and a primer(s) or a short piece of single-stranded DNA that will help 'prime' the copying of the target DNA by providing the empty hydroxyl group on 3' end for sequence-specific incorporation of the dNTPs. The specificity of PCR is driven by the primer design. Most often, primers are carefully designed based upon knowledge of the nucleic acid sequence of target DNA so that it will bind in a specific region of the genome.

Briefly, the steps of PCR include heat *denaturation* to insure that the native double-stranded DNA (dsDNA) is now in a single strand form and ready to be copied, *annealing* of the primer(s), followed by the *extension* of the primer by the incorporation of the purine and pyrimidine, bases which occurs in a sequence complementary fashion (Figure 1). Before the discovery of a heat-stable DNA polymerase from *Thermus aquaticus*, a thermophilic bacterium (Chien et al., 1976), DNA polymerase had to be added after every denaturation step. After one cycle of PCR, the starting amount of DNA has doubled. Given this exponential growth, a theoretical 10^{12} copies are possible from a single target molecule after 40 PCR cycles (Figure 2). PCR automation is possible by the many commercially available thermocyclers that are now commonplace in even the most remote and resource-poor laboratories.

Conventional PCR utilizes end-point detection and sizebased discrimination by gel electrophoresis of any amplified DNA (Figure 3). In an agarose gel, the DNA is exposed to an intercalating agent like ethidium bromide and visualized under ultraviolet light. While conventional PCR offers advantages like increased sensitivity and specificity over traditional methods (e.g., biochemical profiling) for pathogen detection and characterization, there are some substantial limitations. Smearing can occur when too much DNA is loaded on the agarose gel and the resolution between similar-sized DNA amplicons is nearly impossible. Finally, to be semiquantitative, this technique requires to stop the amplification process on the exponential phase of the PCR (when initial DNA quantity but not dNTP, enzyme or primers is the limiting parameter of PCR product formation). Thus, the results with conventional PCR are more qualitative (i.e., absence/presence) than quantitative.

Quantitative Real-Time PCR

The technique of quantitative real-time PCR (qPCR) has existed for over a decade and was largely built upon the fundamentals used in conventional PCR (Saunders, 2009). DNA is still copied but master mix components that produce fluorescence are needed and a more sophisticated thermocycler with fluorescence detectors allow for increases in amplification to be measured as the procedure is happening (in 'real time'). This means that initial concentrations of pathogen DNA (or copy number) and small differences in quantities can be determined because amplification is monitored and data captured during each round of cycling. Figure 4 shows a typical qPCR amplification plot. After 30 or more cycles, DNA amplification reaches a plateau as the master mix components are depleted. Thus, by waiting until PCR completion to view amplification, as is done typically in conventional PCR, only the final plateau is observed and any differences in initial abundance are obscured. Also, eliminating the need to open PCR tubes, containing

Figure 1 The three steps of PCR. The initial double-stranded DNA (dsDNA) piece is denatured to form two single-stranded molecules that can be copied to result in two dsDNA pieces after one round of amplification.

amplified product, means reducing the chance of contamination and time to result by at least 1 h. The differences between conventional (end-point) PCR and qPCR are summarized in Table 1.

With qPCR, fluorescence can be generated in a sequence-specific or non-sequence-specific manner; however, in both cases the fluorescent intensity is proportional to the amount of PCR products produced. The simplest, or nonspecific, approach employs the use of DNA intercalating chemicals like SYBR[®] Green that will emit a strong fluorescent signal when interwoven in dsDNA. Since all dsDNA will be detected, careful examination of the results is necessary to avoid misinterpretation of a positive result when target DNA was not present or to avoid an overstatement of the starting amounts of pathogen DNA. This method requires the analysis of the *melting curve* performed on each PCR reaction after the amplification program has finished. Any double-stranded PCR amplicon will dissociate in a temperature-dependent fashion mostly contingent on the guanine/cytosine content. Postamplification and within the thermocycler tubes are slowly heated to 95 °C while fluorescence is measured. As the doublestranded PCR amplicon dissociates or ‘melts,’ fluorescence will rapidly decrease since any DNA intercalation by chemicals that fluoresce will be lost. The point at which 50% of the DNA dissociates is referred to as the temperature of melting or T_m and is graphically represented as a peak when temperature is plotted against the negative first derivative of the fluorescence signal.

A more specific way of generating fluorescence most often consists of a donor and acceptor molecule linked to a primerlike short piece of DNA, or oligonucleotide probe. When the donor fluorophore or dye is excited by the thermocycler light source, fluorescence is produced and possibly transferred to an acceptor dye. The transfer occurs by fluorescence (or Förster) resonance energy transfer (FRET), a highly distant-dependent interaction where the reporter and quencher molecules must be in close proximity (10–100 Å). With FRET, a photon is not emitted by the donor dye, but rather the energy is transferred to the acceptor molecule. Depending on the strategy, the fluorescence emitted by the donor (e.g., hydrolysis probe) or the acceptor (e.g., hybridization probes) is monitored during the course of the experiment by instrument software.

Many qPCR chemistries exist and still more are under development every day. Some popular ones include hydrolysis probes (e.g., TaqMan[®] probes), molecular beacons, hybridization or FRET probes, and Scorpions[®] probes. Conceptually, hydrolysis probes are easy to understand and provide an excellent example of FRET. In this case, the acceptor molecule is a quencher, a fluorescent dye, or any other molecule that will absorb emitted light energy from the reporter molecule, effectively eliminating or quenching reporter molecule emission fluorescence from being detected by the thermocycler. This requires the wavelength emitted by the reporter to be near the absorbance spectrum of the quencher. Figure 5 provides a schematic illustration. Simply, a hydrolysis probe is constructed to have a reporter molecule on the 5' end and a quencher molecule on the 3' end, which if chosen properly will

Figure 2 Illustration of the power of PCR due to exponential accumulation of PCR product. After 40 cycles of amplification by PCR, accumulation of 10^{12} gene copies is possible when starting with a single copy.

Figure 3 Example of PCR products observed after electrophoresis on 2% agarose gel stained with ethidium bromide. The 5-plex PCR results are shown for seven unknown samples (columns 1–7). Amplicon sizes range from 482 to 136 bp. The unmarked column is a DNA standard or 'ladder' used to confirm amplicon sizes.

Figure 4 Example of a qPCR amplification plot (fluorescence (relative fluorescence units) vs cycles). Since measurements of fluorescence are collected during the exponential phase in qPCR, difference in starting concentration between two samples can be observed. Alternatively, in conventional PCR, samples are often analyzed after the run has finished (plateau phase) resulting in a loss of discriminatory power. Ct (cycle threshold) refers to the point where the fluorescence within a sample crosses the software- or user-defined threshold.

Table 1 Comparison of the attributes of conventional PCR and real-time PCR

Conventional PCR vs real-time PCR		
	Conventional PCR	Real-time PCR
Time to result	~4 h–2 days	~45 min
Analysis	Requires post-run manipulations	Closed tube system
Specificity	From primer only	From primers and probe(s), if used
Sensitivity	Higher detection limit	Lower detection limit
Dynamic range	Short; <2 logs	Increased; >6 logs
Resolution range	>10-fold	As low as 2-fold
Quantitative	No, results not expressed as numbers; size-based discrimination; ethidium bromide staining not very quantitative	Yes, Ct values produced (relative or absolute); increase in fluorescence signal is directly proportional to the number of amplicons generated
Multiplexing	Yes, multiple primers	Yes, multiple primers and fluorophores
Data collection	End point (typically)	During exponential growth phase

prevent any reporter fluorescence being detected until after binding to the DNA strand being amplified. Here, the probe is subjected to the 5' → 3' exonuclease activity of the DNA polymerase enzyme as it encounters the probe. The nuclease activity hydrolyzes the probe separating the reporter and quencher molecules such that FRET can no longer occur, allowing for a photon to be emitted by the reporter molecule and detected by the thermocycler. Hydrolysis probes are a very popular qPCR chemistry that can be applied to single nucleotide polymorphism (SNP) detection for pathogen detection and discrimination.

Multiplex PCR

While the simple presence of a specific microorganism or microbial toxin is often enough for etiologic agent identification, for the linking of human, food, and environmental isolates, and for regulatory agencies to take action to protect public health, sometimes it is desirable to obtain additional information from a single PCR run. Case in point, a patient with flulike symptoms might be suffering from illness due to several different bacterial, viral, or parasitic agents, necessitating the screening for several pathogens. Multiplex PCR can provide a useful tool in this situation. In other cases, pathogen presence might be better determined by targeting multiple areas of its genome. For example, in biodefense work many assays are designed for the simultaneous detection of multiple genes in a microorganism due to concern over the manipulation of an agent's genetic makeup to evade detection by published PCR methods. Multiplex PCR could also be applied to subtyping an organism or genetically closely related organisms at the species or genotype level. Virulence profiling a particular organism might also be desired (i.e., what public health risk is posed by the presence of an organism with particular virulence genes).

The maximum number of targets that can be multiplexed has not been absolutely defined but software is available for 30-plex PCR assays (e.g., PrimerPlex, Premier Biosoft) and commercial kits are available for 20-plex conventional PCR reactions (e.g., Life Technologies, Grand Island, NY, USA). Multiplexing is also available in qPCR assays since nearly all instrumentation provides multiple optical channels that can distinguish different emission wavelengths of light in a single sample. For most qPCR instrumentation, filters embedded in the system provide light tuned to the excitation spectra of specific fluorophores and detect

Figure 5 Concept of hydrolysis probes in qPCR. Hydrolysis probes have a reporter molecule on the 5' end and a quencher molecule on the 3' end. The nuclease activity of the DNA polymerase hydrolyzes the probe separating the reporter and quencher molecules such that FRET can no longer occur allowing for a photon to be emitted by the reporter molecule.

the corresponding emission spectra. One significant limitation of multiplexing in qPCR is the number of channels available with a particular platform (most often four or six). With many assays employing an internal control to judge the validity of a particular PCR run, this means one less channel is available.

Reverse Transcriptase Real-Time PCR

When the beginning target is ribonucleic acid (RNA) and not DNA, an additional step is necessary to convert the RNA to its DNA complement (complementary DNA (cDNA)) using the enzyme, reverse transcriptase. The conversion from RNA to cDNA is necessary since thermostable DNA polymerases are DNA-dependent enzymes. While this is a two-step process, it is possible to accomplish all in a single tube. In terms of pathogen detection, reverse transcriptase PCR is commonly applied to viruses like hepatitis A, *Norovirus*, or *Rotavirus* since their genome is a single-stranded RNA molecule. For viruses like hepatitis E and *Norovirus* that cannot be cultured *in vitro*, real-time PCR (RT-PCR) is a critical tool in detection and diagnosis. An additional advantage of RT-PCR is the ability to assess the viability of bacterial or parasitic pathogens, by detecting the presence of short-lived messenger RNA sequences which are only generated by living organisms. In contrast, standard PCR assays (conventional or real time), which can only detect DNA, offer no direct way to ascertain the viability of any pathogen found in a sample.

Microsphere-Based Suspension Arrays

The presence of pathogens can also be detected using microsphere-based suspension array technology, such as the Luminex[®] xMAP[™] (Luminex Corporation, Austin, TX, USA). Luminex has licensed this xMAP technology to other companies, including Bio-Rad (Hercules, CA, USA), which offers a popular suspension array system, the Bio-Plex 200 (Figure 6). Suspension arrays offer specific, rapid, and high-throughput screening of multiple targets within a given sample. The data output is median fluorescence intensity (MFI), which indicates the presence and amount of analyte in a given sample.

The backbone of the xMAP system is the polystyrene or magnetic microspheres, also referred to as beads, that can be differentiated by unique spectral signatures due to ratios of two (e.g., Luminex 100/200, MAGPIX system) or three (e.g., FLEXMAP

Figure 6 Example of a microsphere-based suspension arrays technology: Bio-Rad Bio-Plex 200 instrument, color-coded microspheres, and laser system used in suspension array work. The unique microsphere color comes from different ratios of two or three distinct fluorophores (ratios signify a particular microsphere region; regions 4 and 42 are shown as examples). The laser system housed within the body of the instrument consists of a red laser that determines the microsphere region and a green laser that generates fluorescence in a positive test sample. APD, avalanche photodiode detector; DD, doublet discriminator channel, discriminates single microsphere from aggregated microspheres; CL1, classify channel, allows multiplexing and detects dye inside microsphere; RP1, reporter channel, quantitates assay in this channel, photomultiplier tube.

3D system) different internally embedded dyes (Figure 6). Each spectral signature defines a microsphere's 'region' and up to 100 (Luminex 100/200, MAGPIX system) or 500 (FLEXMAP 3D system) different regions exist. This means that up to 500 different analytes can be measured within a single sample depending on the instrument model and the combination of different sets of microspheres, providing great flexibility in assay design. Consequently, microsphere-based suspension arrays have superior multiplexing capability over conventional PCR or qPCR since those assays are limited by resolution of band sizes on a gel or the number of fluorescent channels available, respectively.

To detect these analytes, a broad range of customizable bioassay formats is available utilizing capture antibodies, oligonucleotide probe sequences, peptides, or cell receptors covalently attached to the microsphere surface. When antibodies are used, the assay resembles a standard capture sandwich immunoassay (e.g., see section 'Enzyme-Linked Immunosorbent Assay (ELISA)'); however, xMAP assays provide better sensitivity as the traditional colorimetric detection has been replaced by fluorescence detection. Biotinylated detection antibodies can quantify analytes by detecting the fluorescence of biotin-bound streptavidin-R-phycoerythrin (SAPE) conjugates. An immunological approach, in which specific antibodies bind a target protein with high affinity, is particularly applicable to the detection of bacterial toxins. Detection of bacterial nucleic acid is not adequate since toxins may be present in the absence of the source microbe. Pauly and collaborators (Pauly et al., 2009) provide a practical example of xMAP technology applied to immunological detection of bacterial and plant-based toxins, botulinum neurotoxin type A and B, staphylococcal enterotoxin B (SEB), ricin, and abrin in food matrices.

When pathogen DNA is the analyte, PCR amplification is needed before direct hybridization can occur between the oligonucleotide probe attached to the microsphere and a sequence complementary area of the pathogen genome. Typically, this is done through an asymmetric conventional multiplex PCR assay. Asymmetric PCR is performed by using a master mix containing a higher concentration of a biotin-labeled primer than unlabeled primer. If the two strands are amplified nonpreferentially, the reannealing of these strands may outcompete binding to the oligonucleotide probe, producing lower MFI signals. Fluorescence generation is made possible by the attachment of the reporter molecule, SAPE, to the microsphere-probe-PCR amplicon complex (Figure 7).

Using the Luminex 100/200 or FLEXMAP 3D system, a flow cytometer ensures that the microsphere complexes are analyzed individually, with one laser (red) determining the microsphere region and a second laser (green) exciting the SAPE complex to generate fluorescence (Figure 6). The MAGPIX performs a similar analysis, less expensively, by using light-emitting diodes instead of lasers and spreading the microspheres on a monolayer as a charge-coupled device camera records an image requiring fewer microspheres per region. All platforms allow for high-throughput screening in a 96-well plate format (or 384-well plates using FLEXMAP 3D) and all assays, including those requiring PCR, can be completed in less than 6 h.

Figure 7 Experimental setup of the microsphere-based suspension array. The steps of PCR, microsphere hybridization, and analysis are presented.

Microsphere-based suspension arrays have been used to identify the Osero group of Shiga toxin-producing *Escherichia coli* in a single multiplex reaction (Lin et al., 2011), the molecular serotyping of *Salmonella* O-group has been reported (Fitzgerald et al., 2007), along with H antigen typing (McQuiston et al., 2011), the speciation of the fungal pathogen *Aspergillus* (Etienne et al., 2009), and the detection of four different animal pestiviruses (Deregt et al., 2006).

Ligase Chain Reaction

Ligase chain reactions (LCRs) can help researchers detect single base pair differences between target sequences. This is possible because mismatches between two oligonucleotide sequence complementary strands will not allow the thermostable DNA ligase to function, resulting in the absence of that ligated fragment (Figure 8). The LCR process involves adding two adjacent forward primers to the PCR reaction in the presence of DNA template. These two primers are at least one to three base pair(s) away from each other. If the complementary strands (primers added) differ due to an SNP, the ligation cannot occur, and the ligated amplified fragment will not appear in gel electrophoresis. This technology is useful for discriminating among DNA sequences differing in an SNP that is used to cluster (group) bacterial strains.

LCR has been used to detect the quantity of intestinal bacterial components (Tang et al., 2012) by identifying 16S rDNA from several bacteria (*Bifidobacterium*, *Lactobacillus*, *Enterococcus*, *Enterobacter*, and *Eubacterium*) living in the intestine. The researchers compared LCR results with those from with comparative PCR and ligase detection reaction. Another study used LCR as a reproducible molecular identification test of *Brucella* species (Wattiau et al., 2011). The strategy was used to identify multiple genetic markers at the single nucleotide level, resulting in a characteristic capillary electrophoresis profile for 10 *Brucella* species. Because LCR is insensitive to primer interactions in one single reaction, the method can be updated with new future primers without the fear of losing its ability of discrimination due to the addition of more species.

Isothermal Strand Displacement Amplification

Strand displacement amplification is a powerful *in vitro* DNA amplification method that provides an accurate compatible diagnostic nucleic acid assay. In this reaction, four to six primers and DNA polymerase are used to amplify DNA using strand displacement, loop formation, and synthesis of the single-temperature amplification of a specific fragment of a DNA template at a much faster rate than normal PCR (Figure 9). The reaction is based on the ability of a restriction enzyme (example BsoBI) to nick the unmodified strand at its recognition site and the ability of exonuclease-deficient Klenow (Exo⁻ Klenow) to extend the 3' end at the nick and displace the downstream DNA strand (Walker et al., 1992a,b).

Figure 8 LCR. Two forward primers are added to the reaction in the presence of DNA template. The two primers are far from each other by 1–3 base pair(s). If one of the primers does not bind to the template due to mismatch – SNP – the ligation would not occur, and the ligated amplified fragment would not appear in the gel electrophoresis.

Figure 9 Isothermal strand displacement amplification (SDA). During the target generation phase (not illustrated), a double-stranded DNA presenting one modified strand of DNA (green strand) is generated. The addition of restriction enzyme (example *BsoBI*) to the reaction will create a nick in the unmodified strand. The nick will be used by exonuclease-deficient Klenow (Exo⁻) Klenow fragment, represented by a star, to extend (amplify) the 3'-end and displace the downstream DNA strand. The incorporation of dUTP during amplification, which does not inhibit nick formation, is commonly used to prevent carryover contamination. As a result, the iterative nicking and displacement process create many new fragments.

Q-Beta Replicase Amplification

Q-beta replicase is an enzyme originally isolated from bacteriophage Q-beta, which can amplify only a specific oligonucleotide sequence in the presence of midvariant RNA sequence (around 220 nucleotides long, see Glossary). The target oligonucleotide sequence is usually inserted into the 3' end of the probe to be amplified. The sequence acts as a reporter molecule in a hybridization assay: because the probe that hybridizes to the target is DNA, the probe is resistant to RNase III activity and, as a result, it is amplified by Q-beta replicase. This can result in 10 000-fold amplification of 4200-nucleotide singlestranded RNA in 10–15 min at a constant temperature of 37 °C. Unlike traditional PCR, Q-beta replicase does not need changes in temperature for denaturing, annealing, and polymerizing. Each round of replication only takes approximately 20 s and proceeds exponentially, amplifying the target sequence until the number of replicons exceeds the number of the enzyme molecules. Figure 10 shows a general strategy where Q-beta replicase amplification can be used in hybridization assay.

Researchers (Smith et al., 1997a,b) used target capture technology and Q-beta replicase amplification to develop a rapid method for detecting the presence of *Mycobacterium tuberculosis*. Their method was very specific in capturing the target from clinical samples and in amplifying both capture and detector probe for several organism groups. In fact, a prototype instrument platform has been developed to automate the amplification steps inside a closed disposable test pack without the need for a highly skilled technician to operate the reaction (Smith et al., 1997a,b). Using this method also reduces contamination risks while increasing reproducibility and controlling biohazardous waste products.

Q-beta replicase amplification has also been used to identify *Plasmodium falciparum*, human immunodeficiency virus-1, *Cytomegalovirus*, *Chlamydia trachomatis*, and *Neisseria gonorrhoeae* (Cahill et al., 1991). Other molecular biology technologies have been developed to refine Q-beta replicase amplification, decreasing background noise by using reversible target capture (Morrissey and Collins, 1989).

Figure 10 General strategy where Q-beta replicase amplification can be used in hybridization assay. Q-beta replicase enzyme amplifies only a specific sequence in the presence of midvariant RNA sequence (around 220 nucleotides long, which is recognized by the enzyme). When the sequence is inserted into 3' end, the sequence works as a reporter molecule in a hybridization assay. The enzyme produces thousands of copies of the single-stranded sequence in 10–15 min at constant temperature 37 °C. MDV, midvariant RNA.

Gene Identification Using Microarray Chip Hybridization

Another method for gene identification is the chemically modified slide microarray (biochip), which has the ability to bind or capture DNA, RNA, antibodies, or peptides, which can then be detected optically using fluorescent or biotin labels for microarray hybridization. The biochip can screen large numbers of targets and use small amount of reagents with a high level of specificity in a wide range of complex matrices. Several chips capitalize on this sensitive and robust technology.

In Figure 11, the synthesis of DNA sequences or amplification of small fragments of DNA is followed by using a robotic arm to transfer the DNA from a microtiter plate to chemically modified glass slide (printing). The DNA sequence (oligoprobe) usually represents a fingerprint of a gene that has 20–1000 bp. After the printing process, the DNA covalently bonds to the surface of the chip through several chemical reactions. Depending on the technology used, the oligoprobe can also be synthesized *in situ* directly on the chip. The newly developed chip is then taken through hybridization steps with DNA amplified using multiplex PCR (or single PCR), producing fluorescent spots if it is positive (indicating hybridization). The DNA (isolated from tested sample) is labeled with a fluorescent dye such as Cy3 or Cy5 before hybridization. After mixing the labeled probe with printed chip in 50–60 °C for 1 h, the hybridized chip is then washed with several buffers before final readout. The microarray chip is then scanned using laser scanner, and the data analysis is conducted. Genes found in the lysed labeled tested samples light up (give fluorescence) on the chip surface because of hybridization, indicating the presence of the gene; genes absent in the tested samples will not light up.

Gene Expression Using Microarray Chip Hybridization

A second approach is to use DNA microarray hybridization in a high-density array to study gene expression. The printed DNA is usually synthesized from a 60 to 5000 oligonucleotide sequence representing a gene. The chip goes through the same previous steps of allowing the DNA to covalently bind to the chemically modified slide creating a chip. In a different strategy, the DNA oligoprobes can also be synthesized *in situ* directly on the chip (Affymetrix technology, Santa Clara, CA, USA).

Biochip arrays can also be used to analyze the RNA of bacterial strains isolated using two tested different conditions and labeled before hybridization with two different fluorescent dyes such as Cy3 and Cy5. Chip hybridization is conducted, and chips are washed several times with buffer before scanning. The signal intensity of each spot is measured using laser scanners (Figure 12). This process can be efficient in measuring the expression of thousands of genes in just a short time.

Because the chip has the ability to hold thousands of spots (genes, oligoprobes), the amount of gene expression data increases dramatically. The microarray gene expression profile is usually confirmed with other technologies like RT-PCR or microsphere-based suspension arrays. For example, it was possible to quantify the DNA of gastric epithelial cells infected with two different strains of *Helicobacter pylori*: wild type and arginase deficient (Kim et al., 2012). This established that arginase plays an important

Figure 11 Steps involved in preparing a gene chip by using DNA microarray (spotted array) technology.

Figure 12 Steps involved in conducting gene expression analysis using microarrays: (1) tested cell sample will be compared with normal of wildtype cell; (2) RNA isolation; (3) RNA labeling or cDNA amplification and labeling; (4) RNA or cDNA hybridization; (5) chip scanning; (6) hybridization analysis and data mining.

role in helping to establish *H. pylori* infections. Later, the gene expression microarray data were confirmed by qPCR, microsphere-based suspension arrays, and ELISA (Kim et al., 2012). Overall, DNA microarray gene expression is a great tool for screening and understanding the function of networking genes.

Metagenomic Sequencing for Uncultured Bacteria

It is estimated that bacteria isolated using classical microbiology culture methods may represent only 1% of the total living cells in environmental samples (Amann et al., 1995). Therefore, we need other methods for understanding the 99% microbial cells and their communities. Culture-independent genomic analysis (metagenomic) can advance our understanding of these unculturable microorganisms, allowing us to discover new gene functions that are associated with natural populations.

In the past 5 years, DNA sequencing technologies have become cost effective for constructing libraries of DNA sequences representing several natural microbial communities. Metagenomic sequencing originally started in viral communities of the ocean (Breitbart et al., 2002; Venter et al., 2004) and human feces (Breitbart et al., 2003; Venter et al., 2004).

Metagenomic research can not only discover new genes and new natural products, but also study dynamic community interactions among microbes in extreme environments and discover new bacteriophages. Recent work by many research laboratories has showed the effectiveness of metagenomic approaches for understanding microbial habitats, discovering new DNA sequences, and identifying gene functions from unknown microorganisms. Metagenomic research requires cloning and sequencing DNA fragments using the following strategies:

- Screening DNA sequences for the phenotype gene expression using phylogenetic origins of DNA sequences (Brady et al., 2002).
- Screening DNA sequences for 16S RNA, followed by sequence DNA walking to find other novel genes residing near the 16S RNA genes (Beja et al., 2000a).
- Random DNA sequencing of certain genomic parts to reconstruct a DNA sequence map (Beja et al., 2000a,b; Breitbart et al., 2002, 2003).
- Using microarray technology to understand gene expression profiles of unknown microorganisms (Sebat et al., 2003).

The first large-scale metagenomic sequencing (Tyson et al., 2004; Venter et al., 2004) was started using shotgun cloning of environmental genomes inserted into cosmid libraries (Figure 13). This sequencing study revealed the presence of at least 1800 genomic species including 148 previously unknown bacterial phylotypes. New sequences (1.2 million representing 782 new rhodopsin-like photoreceptors) were found. Furthermore, 100-kb plasmids carrying arsenate, mercury, copper, and cadmium resistance sequences were identified. Transfer-related genes were identified in the ocean, suggesting substantial oceanic microbial diversity.

Figure 13 Metagenomic library in *Escherichia coli*. DNA is isolated from microbial communities of groundwater. The DNA is then inserted into the cosmic DNA library (bacterial artificial chromosome (BAC) vector) and sequenced. Inserts can be amplified by PCR, followed by DNA chip fabrication. These chips can be used to characterize microbial communities.

Similarly, a total of 76.2 million sequences representing 103–462 novel genes of natural acidophilic biofilm (Tyson et al., 2004) were found. Microarray platforms representing environmental DNA sequences used to screen 1-kb metagenomic libraries (Sebat et al., 2003) revealed the genetic profile of a metagenomic library.

The metagenomic research was also used to study viruses present in the human gut, which harbors approximately 500 human intestinal microbial species with around 40 predominant species in the total population (Moore et al., 1978; Moore and Holdeman, 1974). The occurrence of viral sequences was found in soil, the intestines of animals and humans, and even sea and drinking water. Metagenomic approaches helped to discover unknown genomic DNA sequences of an uncultured viral community (Breitbart et al., 2003). In fact, a total of 1200 viral genotypes were found, revealing the uniqueness of these microscopic lives. Examples of these viruses are siphophages.

It is important to realize that metagenomic DNA analyses helped to discover many bacterial species and viruses. Metagenomic DNA sequencing is now important in microbial investigation. Identification of new DNA sequences will enhance our lives.

Immunoassays

In vitro immunoassay methods are based on the binding of antibody to antigen. Antibodies are normally immune cells primed to detect and destroy foreign antigens or invading pathogens. The highly specific biorecognition property of antibodies to antigens have made antibodies one of the most indispensable molecules for broad research applications, not only in the diagnosis or detection of pathogens but also in the prevention and treatment of diseases. Immunoassays have been used to detect microorganisms (e.g., viruses and bacteria) and their products such as neurotoxins, which are produced by a variety of microbes, including *Clostridium botulinum*. The detection signals used can be radioactive, colorimetric, or fluorescent. The sensitivity and specificity of the immunoassays is highly dependent on the choice of antibody. Immunoassays are simpler, faster, and easier to perform than other *in vitro* assays. ELISAs, immuno-PCR, immunochromatography assays (ICAs), and flow cytometry are examples of immunoassays.

Enzyme-Linked Immunosorbent Assay

In the past 30 years, ELISA is a commonly applied *in vitro* method for reliable and quantitative detection of bacteria (e.g., *E. coli*, *Listeria*, *Staphylococcus aureus*, *Campylobacter*, *Vibrio cholerae*, *Bacillus cereus*, *Salmonella* spp., and *C. botulinum*) and their toxins in food, water, and environmental and clinical samples (Singh et al., 2013; Banada and Bhunia, 2008). ELISA is a rapid, high-throughput, quantitative immunoassay that is based on an antigen–antibody interaction and detected by an enzyme producing a chromogenic or fluorescent signal. ELISAs are performed in different formats depending on the location of antigen or the antibody on the solid surface. In general, ELISAs are performed in three formats: competitive inhibition, indirect, and sandwich ELISAs (Figure 14).

Competitive ELISA: the primary antibody is mixed in a separate tube with various dilutions of bacteria (or antigen/toxin) and added to the wells containing immobilized antigen. This allows only the free unbound antibody to bind to the immobilized

Figure 14 Diagrammatic representation of ELISA formats: (a) competitive inhibition ELISA, (b) indirect ELISA, and (c) sandwich ELISA. S, substrate; CR, color reaction; E, enzyme; PA, primary antibody; SA, secondary antibody; CA, capture antibody; DA, detection antibody; Ag-Ab, antigen-antibody.

antigen. A secondary antibody-enzyme conjugate and substrate system is added for color development. The highest dilution of cells showing the minimum reaction or equivalent to a background control is considered positive.

Indirect ELISA: the antigen is first immobilized in the wells of a microtiter plate and then incubated with the primary antibody solution. A secondary enzyme-tagged antibody is added to bind to the primary antibody and then the reaction is developed with an enzyme-specific substrate to produce color for the measurement. For a horseradish peroxidase (HRP)-tagged antibody, tetramethylbenzidine (TMB) is used to develop color. If a fluorescent molecule (e.g., fluorescein isothiocyanate, Cy5, Alexa-Fluor) is used, the reaction is quantified by the amount of fluorescence emitted.

Sandwich ELISA: this works similarly to indirect ELISA except that the microtiter plate is first coated with a capture antibody and then the antigen is added into the wells. The reaction is developed using the labeled detection or tracer antibody in either single step or in two steps with the help of an additional secondary conjugated antibody.

Immuno-PCR Assay

The immuno-PCR assay is a powerful tool for toxin detection. This method is similar to the ELISA in that the analyte (toxin) detection is based on formation of an antigen-antibody complex. However, the detected antibody in an immuno-PCR uses a reporter DNA-tagged antibody instead of an enzymetagged antibody. Normal or real-time PCR amplification of antibody-tagged reporter DNA is used for the detection of toxin with increased sensitivity of 10^2 - to 10^5 -fold. Furthermore, sensitivity of immuno-PCR is enhanced by using a biotinylated DNA tag linked to a biotinylated antibody via streptavidin as shown in Figure 15 (Chao et al., 2004).

Figure 15 Schematic representation of the indirect sandwich immuno-PCR assays. Ag, antigen; B, biotin; CA, capture antibody; DA, detection antibody; STV, streptavidin.

Immunochromatography Assays

ICA methods are less sensitive than ELISAs because they use handheld devices and assessment of results is based on quick color development. The intensity of color is directly proportional to the presence of toxin concentration in test samples. ICAs have more field applications due to simplicity of devices and ease of operation, and do not require expensive instruments to perform the test. Lateral flow assays (LFAs) and affinity immunochromatography (AIC) are examples of ICAs.

LFAs: LFAs are handheld devices or a dip-stick method performed on a nitrocellulose strip. The LFA tests rely on a capture antibody–toxin–detector antibody interaction. In the lateral flow test, a line of a capture antibody is printed onto the nitrocellulose support, and the other reagents (e.g., detector antibody, buffers, and control antibodies) are dried onto a reagent pad. A drop of the toxin sample is applied to the reagent pad (sample zone) resulting in hydration of the reagents and allowed binding of toxin with detector antibody. Thus, the bound toxin with detector antibody migrates from the sample zone to the detection zone where it is trapped by the capture antibody. This trapping step results in concentration of the toxin bound to a labeled secondary antibody as a complex in a zone visible as a colored line (Figure 16) (Ching et al., 2012). Common labels include colloidal gold, resulting in a red

Figure 16 Schematic representation of a lateral flow device (LFD). The actual LFD (right) shows an example of positive detection of BoNT/A and B serotypes with the control line. Reprinted from Ching, K.H., Lin, A., McGarvey, J.A., Stanker, L.H., Hnasko, R., 2012. Rapid and selective detection of botulinum neurotoxin serotype-A and -B with a single immunochromatographic test strip. *J. Immunol. Methods* 380, 23–29. Copyright © 2012 with permission from Elsevier.

line, or various colored latex spheres conjugated to the detector (second) antibody. LFAs have significant advantages (e.g., self-contained, quicker, and do not require sophisticated equipment and an expert analyst) compared to other detection methods. Thus, they are ideal for field situations. LFA kits have been introduced in recent years for the detection of *E. coli* O157, *Salmonella* spp., *Listeria* spp., and *C. botulinum* from enriched food samples.

AIC assay: in this type of assay, a column is preloaded with matrix. The biotin-tagged antibody is mixed with a toxin sample, incubated for 30 min, and then loaded on to the column. The column was washed and passed through a solution of avidin-tagged HRP detection antibody. Then an insoluble solution of HRP-specific TMB substrate is added for color development (Figure 17) (Attree et al., 2007). The intensity of the color is directly proportional to the toxin concentration in the sample.

Flow Cytometry

The fluorescence sandwich immunoassay is a solid-phase immunoassay in which the capture antibodies are immobilized on Sepharose beads and used to detect and quantify toxin with the help of flow cytometry. This assay measures fluorescent intensity of individual particles in a flowing stream and can collect information in multiplexed format by using different color-coded Sepharose beads. A pentaplex flow cytometry assay was developed to test ricin, BoNT serotype A and B, abrin, and SEB in a variety of food matrices by applying fluorescent magnetic beads (Pauly et al., 2009). The sensitivity of flow cytometry assays can be further improved by using single domain antibody (sdAB) (Goldman et al., 2008), three heavy chain-specific antibodies, and introducing

Figure 17 Schematic representation of AIC assay. (a) Prepare a column matrix by preincubation of toxin with biotinylated antibody for 10–30 min and pass antigen–antibody complex through AIC columns. Add solution of HRP-labeled antibody tagged with avidin that binds to the biotin. Finally pass through an insoluble substrate (TMB) for the HRP, which produces a visible band. (b) The intensity of color in AIC columns depends on toxin concentration. Streptavidin poly Horse Radish Peroxidase (pHAP). Reprinted from Attree et. al., 2007. J. Immunolo. Method. 325, 78–87. Copyright 2012 with permission from Elsevier.

an automated fluidic platform to process the sample, washing away the sample matrix to get a higher sensitivity for BoNT/A heavy chain (Ozanich et al., 2009).

Freshwater Habitats[☆]

Laura G Leff, Kent State University, Kent, OH United States

Overview

Freshwater environments are ubiquitous and critical to human success as sources of drinking water, conduits for waste materials, aesthetical and recreational purposes, among other uses. The great diversity in form and function of freshwater systems results in significant differences in microbial community structure and processes. Water flow, water depth, light level, nutrient inputs, pH, plant communities, and numerous other factors all influence the microbial ecology of freshwater (aquatic) ecosystems.

The presence of water dictates several key common properties of these environments, as do the interactions with the surrounding terrestrial environment within the watershed. Water provides a means for dispersal of organisms, transport of materials, and structural support while at the same time limiting light availability as depth increases, altering temperature regimes, and impacting oxygen concentrations. Some freshwater environments are fueled predominantly by allochthonous fixation of C while others are dominated by autochthonous C fixation. At the same time, microbial cells may enter aquatic ecosystems from outside sources and inter-mingle with autochthonous organisms.

Freshwater habitats are profoundly impacted by anthropogenic disturbance such as alterations in hydrology, land use, disposal of waste materials, contamination with fertilizers, heavy metals, xenobiotic organic compounds, introduction of exotic species, etc. Global climate change also has great potential impacts on freshwater resources through increases in carbon dioxide, elevated temperatures, an increase in sea level, and alterations in precipitation and snow melt seasonal patterns. Some of these are predicted to impact hydrology of freshwater systems while others may directly impact biota. The combination of these effects is predicted to alter freshwater habitats and thus, there is the potential for the microbial ecology of the systems to also change.

The central importance of bacteria, fungi and other microorganisms to biogeochemical cycles in freshwater systems is clear. There is also tremendous variability among freshwater systems and the diversity of microorganisms in these systems is still relatively understudied compared to soil and marine environments. Temporal changes in microbial community composition and diversity can be large and freshwater environments play host to communities of bacteria that are, in many ways, distinct. The number and diversity of freshwater systems that have been investigated continues to grow. Utilization of new methodological approaches is one driver of the expanding knowledge base.

As in other fields of microbial ecology, methodological advances, particularly those that facilitate linkage of community structure and function continue to have an impact on our understanding of freshwater systems. Particular advances have been made in the linkage in structure and function as it relates to key aspects of the nitrogen cycle. In addition, many microbial ecology concepts (such as those related to community assembly) and topics (like metagenomics) that have previously been only occasionally applied to freshwater systems are becoming more established although are still dramatically understudied compared to marine systems. Yet, freshwater studies may achieve more mechanistic insights because of their amenability to experimental manipulation and intensive spatiotemporal sampling. Functional genes, such as those involved in nitrogen fixation, denitrification and nitrification, have been studied with increasing frequency both in terms of diversity and quantity. Some studies of microbial gene expression (such as expression of *nif* genes for nitrogen fixation) in freshwater systems have also been conducted.

Although much focus is placed on microbial ecology in “natural” freshwater systems, be they pristine or impacted to a degree by humans, there is a much needed growing exploration of other systems. Most notable are those in urban areas as well as freshwater systems that are being restored or remediated. Studies of agricultural and wastewater impacts on microbial ecology are generally more common than those related to urban systems. Human impacts on freshwater systems are profound and part of the process of restoring natural functions involves creation or alteration of such systems. Such modifications include creation of artificial wetlands as a response to wetland loss or restoration of streams (for example, morphological modifications). In streams, management strategies may focus on achieving specific biological metrics (as related to fish communities, for example) or physical characteristics of the stream channel. The effects of such management on microbial community function and structure is largely unknown. Generally, study of the structure/function of the microbial community and biogeochemistry in created or restored freshwater systems is still in its infancy.

The three main types of freshwater habitats are discussed below and include wetlands, lakes, and lotic ecosystems (streams and rivers). Wetlands are arguably the least studied of these systems relative to structure of the microbial community although the functional role of microorganisms in wetlands and other freshwater habitats is well established. For each freshwater habitat type, the nature of the hydrology, geographic location and climate, and origin contribute to the large variations seen in ecosystem properties. The role of allochthonous versus autochthonous sources of organic compounds, nutrients, and microbial cells also varies among ecosystem type along with the contribution of plant detritus to the food web.

[☆]*Change History:* April 2018. New content was added to the overview section (3 paragraphs), new content was added to section III (lakes), Figure 4 was modified, new content was added to section IV (streams and rivers), IV Emerging Directions and Approaches is new content, references were added, and text was edited for clarity and accuracy.

This article is an update of L.G. Leff, Freshwater Habitats, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 190–204.

Freshwater Wetlands

Wetland Types and Properties

The nature of freshwater wetlands varies based on hydrology, origin of the wetland, plant community composition, and other features; these variations in turn affect the microbial communities of the environment. This complexity also limits the number of generalities than can be drawn about the microbial ecology of these ecosystems.

As landscape features, wetlands help to ameliorate environmental contaminants and manage flooding. At the same time, wetlands are highly threatened environments. For example, the percentage of wetlands in the continental United States is estimated to have declined by about 50% since pre-settlement times. Wetland loss in Europe as well as parts of Asia is thought to be much greater. The importance and vulnerability of freshwater wetlands leads to regulations in many countries regarding the use and destruction of wetlands. This, in turn, contributes to the issues associated with the definition of a wetland.

From a basic point of view, wetlands are shallow aquatic communities dominated by plants in which detritus plays a central role in the food web. From a stand point of delineation, the definition of wetlands is more complex and has been the subject of great debate. Overall, wetlands, for purposes of this article, can be defined as systems with hydrophytes (wetland-type plants), hydric soils, and, during the growing season, periods of standing surface water or water-saturated soils. The duration and depth of standing water varies greatly among wetlands and, within in a wetland, seasonally and from year to year.

The hydrology, origin, and geographic location of the wetland are a major determinant of plant community structure which in turn influences the microbial communities. Wetlands include those on the fringe of larger bodies of water, such as around the Great Lakes of the USA, prairie potholes, marshes (including freshwater tidal marshes), swamps, riparian zones and floodplains along rivers, bogs, playas, billabongs, etc. Each wetland is connected to the surrounding terrestrial environments in a variety of ways and they also can be connected to marine or other freshwater systems. For example, nutrients from a fringing wetland can be transported into lakes linked seasonally by water.

Wetland environments can be stressful and exhibit large seasonal changes in hydrology including periodic drying. This effect, coupled with the development of areas of low oxygen concentration, low redox potential, and wide array of different types of organic compounds, which in some cases, accumulate in the system, defines the microbial ecology of the wetland.

Human use of wetlands is also an important determinant of wetland function and biogeochemistry. Wetlands serve as sources of flood abatement, carbon sequestration, and phytoremediation and support a rich and unique flora and fauna. Wetlands are also created and used by humans for production of food, such as rice, fish and crayfish.

Overall, critical features of wetlands that affect the ecology of microorganisms are:

- Important role of plants and detritus in the food web,
- Critical role of hydrology which varies greatly among wetlands of different types,
- Seasonal variation in the extent of hydration of soils,
- Profound human impact on wetland extent, nature and hydrology,
- Creation of new wetlands, perhaps with different ecological properties, to replace wetlands lost through human use or to serve as sites of food production.

Microbial Processes

The importance of microbial processes in wetlands manifests itself in the biogeochemistry of these systems and the central role that detritus decomposition plays in the food web. Dissolved organic matter (DOM) is a major component of the organic matter pool and is made available to higher trophic levels by microorganisms. In some wetlands, often referred to as dystrophic, dissolved organic carbon (DOC) concentrations can be substantial and “stain” the water brown to black because of large amounts of humic substances. These wetlands, such as bogs, are often characterized by unique plant communities, including, in some cases, the occurrence of *Sphagnum*, formation of peat, and low pH.

Inundation with water creates anaerobic conditions in wetland soils providing the opportunity for alternative metabolic processes. The strong seasonality in the hydrology of many types of wetlands creates circumstances where there is flooding and corresponding chances for anoxia in lower layers of the soil at some times of the year, but not at other times (Fig. 1). This creates seasonal patterns in key microbial processes, such as methanogenesis and denitrification.

Plants play a seminal role in determination of microbial processes in wetlands including their impact on soil conditions, the detrital pool, and the oxygen status of the soil. Plant roots lose oxygen (from air-filled tissue in wetland plants called aerenchyma) to the surrounding soil altering the otherwise anaerobic status of the soils. The occurrence of oxygen is variable both spatially and temporally and, thus, the optimal conditions for growth of a particular microorganism may not always be present.

The C cycle of wetlands is characterized by a mixture of anaerobic and aerobic processes occurring at different locations or at different times. Often these processes can occur in spatially close proximity to each other in different portions of the soil. Fermentation is a common process in wetlands and appears to play a critical role in providing suitable organic compounds for other anaerobes. Methanogenesis in wetlands tends to be better studied than fermentation and can result in release of bubbles of methane gas (referred to as swamp gas). Methane emission from wetlands globally is quite large and is of particular interest because of the role of methane in global climate change and the possibility of management of methane entrance into the atmosphere. Quantification of methane production by wetlands reveals that there is substantial variation among wetland types and geographic locations.

Fig. 1 Temporal changes in availability of alternative electron acceptors in wetland soil.

Properties of the N cycle in wetlands are highly variable depending on plant community type and hydrology. The sediments of wetlands play a critical role in the N cycle. N can be a limiting nutrient in wetland soil and depending on the N pool, N fixation will be more or less important. For example, the floating fern, *Azolla*, has a symbiotic nitrogen fixing cyanobacterium (*Anaebaena*). In wetlands created for rice cultivation the *Azolla: Anaebaena* may help rice production. In addition, in some cases, wetland fringing plants, such as alder (*Alnus*), may host nitrogen fixers that can impact the wetland N cycle. It appears that nitrogen fixation also does occur in association with wetland plants (such as some grasses), however, the organisms responsible of this activity defy cultivation and thus the amount of information on them is still relatively limited.

Denitrification is a potent source of N loss (as N_2) because of the extensive amounts of organic matter and anaerobic zones. The large amounts of N applied to landscapes can work their way into wetlands and perhaps these ecosystems can serve as N sinks in the global N cycle. Denitrification may be limited by low pH and thus loss of N in this fashion, in some wetlands, is more restricted than others. Hydrology also includes the potential for denitrification and the availability of nitrate. However, generally denitrification results in a major loss of N from wetlands that exceeds inputs from nitrogen fixation.

Nitrification plays a critical role in removal of ammonium from the soil which tends to accumulate because of ammonification. Aerobic zones supportive of nitrification occur in the top most layer of soil as well as in aerobic patches caused by plants in the rhizosphere. In some wetlands, ammonium is converted into ammonia which can be lost to the atmosphere and generally ammonium diffusion rates through wetland soil are a limiting process. In acidic wetlands, nitrification may be slower relative to other wetland types. Bacteria that oxidize ammonium anaerobically (anammox) are present in freshwater wetlands although their role in the N cycle of these systems is largely unexplored.

Sulfur transformations also occur in wetlands, although S is generally not a limiting nutrient and thus it is less frequently studied in freshwater wetlands. One manifestation of these transformations is the distinctive rotten egg smell from release of hydrogen sulfide when anaerobic wetland sediments are disturbed. Compared to marine wetlands, sulfide emissions from freshwater wetlands are much lower because S concentrations in marine systems greatly exceed those of freshwater systems. Sulfides produced by sulfate reduction can subsequently be oxidized by autotrophs. Sulfides that are not oxidized are toxic to plants and can precipitate with metals.

Phosphorus lacks the alternate oxidation states of N and S but is often a limiting nutrient in freshwater ecosystems. Some wetlands, such as bogs, are exceptionally nutrient limited while others receive P input from fertilizer and other sources. Both organic and inorganic P contribute to the P pool and insoluble P complexes can be formed that affect bioavailability. For example, P can complex with iron or calcium or attach to clay or peat. In particular the sorption of P to clay can form complexes which may be carried into wetlands. When this material sediments, it helps make P available to the wetland plant community and allows the wetland to retain P.

Microbial Communities

Relative to other freshwater systems, the amount of information on microbial community structure in freshwater wetlands is relatively limited. Although microbial mediated processes are widely studied, as described above, the underlying communities

responsible for a particular function are unknown to varying degrees with more information available on methanogens, methanotrophs, and denitrifying bacteria, for example, relative to other functional groups, such as nitrogen fixers.

Although the role of fungi as decomposers of plant tissue is widely known, there is much less information available on the mycorrhizae associated with wetland plants. However, the potential importance of mycorrhizae in the success of plants may be particularly relevant in wetlands that are nutrient limited, such as bogs and fens, and can also be important to phytoremediation.

Although the number of investigations of bacterial diversity and community structure in freshwater wetlands is relatively limited, studies have revealed, that for the wetlands examined, *Proteobacteria* (Alpha, Beta and Gamma as well as the Delta *Proteobacteria* which are perhaps not as well represented in lakes and streams), the *Acidobacteria*, and the *Verrucomicrobia* are major constituents. The *Acidobacteria* are a widespread but largely understudied group because of limitations in our ability to culture these organisms. Likewise, there are few cultures from the group *Verrucomicrobia* with some of the major subgroups in this taxon having virtually no cultured representatives. *Verrucomicrobium* and other prosthecate bacteria are among the most well known members of this widespread and understudied group.

Amongst the Archaea, the occurrence of methanogens in wetland is the most often studied especially in light of the role of methane as a gas contributing to global climate change. In anoxic wetland soils, methanogenesis is a critical biogeochemical process and varies seasonally; both the availability of suitable substrates and nutrients impact methanogen function. The nearby occurrence of methanotrophs in oxic areas and their oxidation of methane greatly impacts methane release.

The role and diversity of protozoa in wetlands is largely unknown. Generally, the impact of protozoa as bacterial consumers is great in aquatic environments and less so in soil. There is at least some evidence that protozoan community composition can be very different than that of other freshwater habitats. The number of protozoa and consequently their impact on bacterial numbers fluctuates seasonally in temperate wetlands.

Anthropogenic Disturbance

Human impacts on wetlands are varied and, among these, perhaps the most important is the vast global destruction of wetlands. This leads to the phenomenon of wetland construction whereby new wetlands are created to replace those lost due to conversion into other uses (agriculture, construction, etc.). How well these created wetlands duplicate natural conditions and function as desired is variable and debatable. Hydrological modifications, to reduce flooding for example, are also common and considering the key role of hydrology in wetland microbial ecology undoubtedly greatly impact microbial processes.

Wetlands are also used for various agricultural and horticultural activities, such as peat mining and production of plants, such as rice. Like other freshwater habitats, impact of humans on water quality can translate into these environments. One manner in which some environmental issues may be addressed is through phytoremediation. Phytoremediation may be accomplished in either natural or constructed wetlands and potentially can remove xenobiotic compounds from water systems. Critical features for the success of phytoremediation in wetland include the redox potential, extent of above and below ground plant biomass, and hydrology.

Invasive species represent one area in which the effects on microbial communities in wetlands remains largely unknown. Of particular importance, are changes in native plant communities associated with the invasion of exotics, such as reed canary grass (*Phalaris arundinacea*), purple loosestrife (*Lythrum salicaria*), and alligator weed (*Alternanthera philoxeroides*). The role of plant communities in wetlands is a critical defining feature and thus alteration of the plant communities towards potentially nearly monospecific stands of exotic species is of great concern. Native plants are often out competed by exotic species of plant, perhaps resulting in a loss of the microbiota associated with the native plants (such as mycorrhizae), as well as an alteration in many other factors, such as soil moisture, quality and nature of the detrital pool, etc. In general, invasive plants are known to alter C, N, and water in soil, including altering N availability and fixation, and have differences from native species in productivity, growth form, chemistry, etc. Although the role of these differences in wetlands is less well studied than in terrestrial environments, the potential for a substantial change in wetland microorganisms is clear.

Lakes

Properties and Types

Like wetlands, lakes originate in various ways and the nature of their origin, hydrology, and morphometry impact environmental conditions and biotic functions. Basic morphometry is of particular importance because of the limitations that depth imposes on macrophyte success, the extent of the littoral zone, and because of impacts on the relative contributions of allochthonous and autochthonous production. Lake processes are very much dependent on the properties of the surrounding watershed, as those of other freshwater ecosystems. Lake age is also highly variable and depends on the lake type. In many ways, human impacts are poorly understood and not always recognized because so many key processes are hidden beneath the water column and thus unseen by the lay person.

One of the most critical determinants of the microbial ecology of a lake is its trophic status which ranges from eutrophic to oligotrophic (with various modifications of the terms, such as hypereutrophic). The trophic status of the lake profoundly influences the food web, biogeochemistry and other processes. Oligotrophic lakes are characterized by low nutrient concentrations and low primary production (as reflected in the low abundance of phytoplankton in the lake). Eutrophic lakes, in contrast, are characterized

by high nutrient concentrations and correspondingly high primary production. There is a gradient of trophic status between these two conditions with lakes in the middle of the gradient referred to as mesotrophic. The trophic status is the main determinant of the number, biomass, production, and diversity of microorganisms because of the differences explained above and their corresponding impacts on oxygen concentration.

Lakes, or lentic ecosystems, are also characterized by their stratification and mixing properties. In temperate zones, many lakes are dimictic with thermal stratification in winter and summer and turnover events in spring and fall. In some regions, there are lakes with permanent stratification called meromictic lakes, such as those where salt and fresh water combine, or those that are particularly deep, while other lakes never stratify. Amictic lakes are permanently ice covered, such as lakes found in Antarctica. Other lakes are monomictic with stratification once per year or polymictic with mixing and stratification multiple times throughout the annual cycle. The pattern of stratification and mixing depends on latitude and lake properties.

Seasonal stratification in temperate areas occurs because inputs and outputs of heat occur primarily at the surface of the lake. In such temperate zones, the heating of surface waters in summer creates a warm, circulating surface water pool (the epilimnion) with colder, undisturbed water below the thermocline in the hypolimnion (Fig. 2). As fall begins, the surface water cools and at some point reaches the same temperature as the underlying water; this results in a loss of density differences and as this surface water becomes cooler and denser it sinks causing the layers to mix or turn over.

In a dimictic lake that is productive (eutrophic) during times of thermal stratification (Fig. 2), the hypolimnion can be depleted of oxygen through biological activity. This happens when this layer is separated from and not mixing with the overlying water; biological activity in this confined layer resulting from decomposition can be great enough to deplete oxygen. This creates microbiologically important gradients with depth that can result in some interesting juxtapositions of biogeochemical processes as described below.

Another main way of categorizing lakes is their vegetation; with macrophyte dominated systems versus algal dominated systems representing alternative stable states. The dominance of macrophytes versus algae greatly influences the trophic interactions and paths of C transfer. The two alternative states which can occur in shallow eutrophic lakes are 1) clear water with abundant macrophytes or 2) less clear water because of phytoplankton abundance without abundant macrophytes. The clear water state is often associated with desirable fish and invertebrate communities, while the turbid water state tends to have lower diversity and undesirable algal blooms. These alternate states represent a shift in the lake community and may result from competition from nutrients, light limitation and turbidity, allelopathy or other factors. If the food web of a lake (such as by removal of macrophytes) or P concentrations are altered, it is possible to shift the state of a lake.

Overall, important lake properties that influence the microbial ecology of the ecosystem are:

- The trophic status of the lake (as determined by concentrations of N and P) and its point along the oligotrophic: eutrophic gradient.
- The morphometry and size of the lake which influences the size and relative contribution of the littoral zone and allochthonous inputs.
- The status of macrophytes in the lake; whether it is algal dominated or macrophyte dominated.
- The stratification and mixing patterns over the course of a year.

Fig. 2 The water layers and temperature profile in a typical seasonally stratified lake.

Microbial Processes

Both stratification and trophic status are major determinants of what microbial processes happen and where they happen. Stratification in a eutrophic lake, in particular, can ultimately lead to large, seasonal anoxic zones which greatly impact microbial processes as well as macrofauna. Occurrence of these so-called “dead zones” also significantly impacts lake quality as it may limit fish community success. The nature and extent of stratification as well as nutrient availability creates obvious differences in C and nutrient cycles amongst different lakes.

One emerging area of lake microbial ecology is the insight that can be obtained by comparison of different lakes. In some cases, a time can be exchanged for space to look at temporal succession while in other cases lakes with different levels of anthropogenic disturbance can be compared. Lakes can also serve as sentinels for global climate change; this work is facilitated by comparative studies, use of sensors and global networks, like the Global Lakes Observatory Network (see “Relevant Website section”).

C cycle

Taken from a simplistic point of view, lake food webs include both a grazer “food chain” and a microbial “food chain” or microbial loop (Fig. 3). The relative amount of C transferred through these two components varies from lake to lake and within a lake (for example, near shore versus off shore). The dichotomy between these two paths is also reflective of the role of detritus in the system with the microbial loop reliant on the extensive dissolved portion of the detrital pool.

The occurrence of anoxic areas in the hypolimnion and benthos creates opportunities for the use of alternative electron acceptors at the appropriate depths within a lake. These processes can effect the C cycle; for example, methane is generated in these anoxic areas by anaerobic archaea and then can be utilized by methanotrophs in the overlying oxic area (the epilimnion). Likewise, fermentation occurs in the anaerobic zones resulting in a variety of small organic compounds for use by other microbes.

On macrophytes, extensive biofilms (often in limnology, such biofilms are referred to as periphyton) can form which may serve as competitors for nutrients with phytoplankton. These biofilms are complex structurally and feature diatoms interconnected by the extracellular matrix as well as cyanobacteria and heterotrophic bacteria. Some components of this assemblage penetrate into the macrophyte tissue while others are more loosely associated. Within these biofilms, release of extracellular organic compounds by algae supports bacterial growth and bacteria, in turn, release carbon dioxide and degradative enzymes. The surface area of macrophytes in a lake can be extensive depending on its state, depth, and relative littoral zone size. Thus, the role of these macrophyte-associated biofilms in nutrient acquisition may also be great.

N cycle

The N pool in lakes includes both inorganic and organic components that are utilized and transformed by microorganisms. Cyanobacteria, such as *Anabaena* and *Aphanizomenon*, are important nitrogen fixers especially, but not always, those that produce heterocysts. For example, members of the Oscillatoriaceae are also common and important in lakes but lack the ability to produce heterocysts. N fixing cyanobacteria are a valuable surface for attachment of bacteria and the heterocysts may create microzones of low oxygen concentration creating specialized bacterial niches. There is limited information on the importance of heterotrophs, such as *Azotobacter*, in nitrogen fixation in lakes. This is perhaps a result of the assumption that this process might be limited by the availability of labile organic compounds.

Nitrification in lakes occurs in aerobic zones and thus may be limited in the deeper sediments. In addition, specific dissolved organic compounds (such as tannins) may inhibit nitrification. Denitrification is important in areas with oxygen depletion (although it can also occur aerobically) such as the sediments of littoral zones of lakes and the hypolimnion of stratified eutrophic lakes. The ability to denitrify is widespread among different types of bacteria, including *Pseudomonas*, *Bacillus*, and *Achromobacter*.

Fig. 3 Stylized and simplified food web in the water column of a lake illustrating paths of C transfer in grazer and microbial food webs; green arrows indicate grazing while brown arrows indicate production and use of detritus in the form of dissolved organic matter. Note within the protozoa box, multiple trophic transfers may occur.

P cycle

Each elemental cycle in the lake is intertwined with other cycles; this is illustrated, in particular, for the P cycle. Lake sediments are a major source of P in lentic ecosystems and P is often a limiting nutrient; additions of N and P lead to eutrophication which greatly impacts biotic processes. Most of the P in a lake is contained in the biomass and in organic compounds and total P concentrations vary considerably from hypereutrophic to ultra-oligotrophic lakes. Because P is often a limiting nutrient much attention has focused on internal loading from the sediments; the process by which sediment P is released into the water column. Mobilization of P is facilitated by bacteria such as *Pseudomonas* and *Chromobacterium* but chemical processes are dominant. Specifically, complexation with metals plays a major role in the lake P cycle; for example, phosphate can be released from ferric phosphate under anoxic conditions. Formation of iron sulfide associated with sulfate reduction can reduce the complexation of phosphate by iron.

Microbial Communities

The amount of information on lake microbial community structure has increased dramatically over the years. Prokaryotic communities have been studied in a variety of lakes of different sizes and trophic status. These studies have revealed information about the dominant bacterial taxa as well as differences between lake and marine communities.

The water column microbial community is distinctive in function and also structure from the benthic community. Depending on the water depth, the benthos may be a viable habitat for phototrophs. Often the benthos may be anaerobic (especially below the sediment surface) even if the overlying water is oxygenated providing opportunities for methanogens and denitrifiers.

Phototrophic prokaryotes fill a particular series of niches in the lake environment based on their physiological needs and pigments used. Cyanobacteria are abundant and can grow to nuisance levels especially in eutrophic lakes with abundant P. The gas vesicles produced by cyanobacteria contribute to their buoyancy and ability to maintain position in the water column which ultimately enhances their success. Many of these cyanobacteria can fix nitrogen resulting in undesirable blooms which have negative impacts on water quality. For example, *Microcystis*, which is abundant worldwide, produces microcystins which are of great concern for water quality from both a drinking water stand point and the success of aquatic animals. The hepatotoxins produced by *Microcystis aeruginosa* have damaging effects on the livers of mammals and control of this organism can be an important goal of lake management.

In many countries around the world, occurrence of toxin producing cyanobacteria in lakes is of concern. Cyanotoxins produced include hepatotoxins, neurotoxins, dermatotoxins, and endotoxins which negatively impact water quality. Arguably the toxin of most concern in cyanobacterial harmful algal blooms are microcystins and much effort has focused on *Microcystis aeruginosa*. Efforts are made to control the blooms of cyanobacteria by biomanipulation (increasing grazing on the bacteria, top down control) and by decreasing nutrient availability (bottom up control). Bioremediation via microcystin degrading bacteria is also a potential tool in removal of toxins from water for consumption. The introduction of exotic species of cyanobacteria that produced toxins, such as *Cylindrospermopsis raciborskii*, can compound the problems associated with these organisms by introducing new types of undesirable algae into lakes.

Beyond the cyanobacteria, green sulfur, purple sulfur and purple non-sulfur bacteria can occupy niches in lakes. Their niches occur in stratified lakes in which the anoxic hypolimnion has adequate levels of light to support their growth and, for the sulfur bacteria, hydrogen sulfide in the concentrations needed. The occurrence of these ideal conditions creates relatively narrow bands in the water column where these organisms are abundant certain times of the year in temperate dimictic lakes. Factors including oxygen concentrations, temperature and light penetration are determinants of the vertical stratification of different types of photoautotrophs in lakes. The importance and perhaps diversity of non-oxygenic phototrophs is greater in lakes with permanent stratification; for example, in permanently frozen lakes of Antarctica or in meromictic lakes in other regions.

For the bacteria, overall, Beta-Proteobacteria appears to be the dominant group in freshwater making the community of freshwater systems distinct in some ways from marine systems. The Beta-Proteobacteria includes the freshwater ammonia-oxidizing bacteria and are common in high nutrient conditions and biofilms. In large oligotrophic lakes there is increasing evidence for the importance of the Actinobacteria. The Alpha-Proteobacteria are found in peak numbers, in many cases, under more oligotrophic conditions, and can be correlated with chlorophyll concentration and have a preference for labile organic matter. In addition, the gamma Proteobacteria are abundant as are the Cytophaga-Flavobacterium-Bacterioides cluster and Verrucomicrobia. The Cytophaga-Flavobacterium are specialized for utilization of high molecular weight organic compounds and thus may exhibit spatio-temporal patterns of abundance related to the occurrence of molecules of this type.

The composition of the bacterial community and relative importance of each of these major groups can vary considerably among lakes as related to variations in trophic status, pH, temperature, and nutrient concentrations. Likewise, there are often differences in the relative abundances of major groups between the hypolimnion and the epilimnion in stratified lakes as well as between different portions of lakes (for example, areas that are shallower and close to riverine inputs might have a different community composition than off shore sites).

Fungi perhaps play a less important role in many lakes than other microorganisms because the role of plant detritus in some lakes is less significant. Aquatic fungi are important in littoral zones and in the degradation of macrophyte tissue. Many fungi that are encountered on plant material may be of allochthonous origin having colonized the tissue prior to submergence. However, the overall contribution of C from littoral zones and macrophytes is highly variable among lakes depending on size and morphometry. In many lakes, pelagic processes and in particular algal-bacterial coupling may be the central component of the microbial food web.

Algae in lakes have been studied for many years and are responsible typically for most of the C fixed in many lakes especially those that are large and too deep for growth of rooted macrophytes. Algal communities are diverse and different species fill varying ecological roles based on differences in motility, habitat preferences, and palatability to aquatic animals. Algae can be directly consumed by grazers and support bacterial growth via release of exudates (Fig. 3). In addition to prokaryotic algae, diatoms, green algae, chrysophytes, and dinoflagellates are common lake microbiota while some important marine groups (red and brown algae) are not as common in freshwater lakes. The relative balance between the prokaryotic algae (cyanobacteria) and eukaryotic algae depends on many factors including light and nutrient availability. The stoichiometric ratio between N and P is a particularly critical factor.

Protozoa play an important role in the microbial loop of lakes and are major consumers of bacteria. There is tremendous diversity of freshwater protozoa including organisms that are mixotrophs; protozoa that are photosynthetic and also consume prey items, such as bacteria. There are large spatio-temporal changes in the distribution and abundance of different species which is facilitated by the ability of some species to form cysts to persist undesirable conditions. There is vast morphological and function diversity amongst freshwater protozoa. Overall, from an ecological stand point, the smaller heterotrophic flagellates may be the most important bacterial grazers.

Anthropogenic Disturbance

Human impacts on lakes include those that are direct and those that are indirect. Indirectly, humans impact hydrology and nutrient loading into lakes while anthropogenic disturbance also has direct effects through invasive species, for example. Other anthropogenic disturbances of concern that may impact microbial ecology include changes in lake water level, decreasing pH from acid precipitation, input of gasoline additives from boating, heavy metal pollution (such as mercury), dredging, etc. An area of emerging concern in many aquatic ecosystems is the occurrence of plastic debris; microplastics are well studied in marine ecosystems and also are abundant in the Great Lakes, particular Lake Erie. Few studies have examined the occurrence of microplastics in other lakes.

Invasive species in lakes range from fish to invertebrates to plants to zooplankton. Examples include the zebra mussel (*Dreissena polymorpha*), water hyacinth (*Eichhornia crassipes*), and Eurasian watermilfoil (*Myriophyllum spicatum*). There are numerous other examples of invasive species including the widespread practice stocking of fish into lakes for fishing purposes. The role of exotic species in altering the food web and microbial processes in some cases is largely unknown while in other cases the impacts are at least partially explored. For example, the zebra mussel has invaded areas such as the Great Lakes in North America and greatly alters the environment by clearing the water while filter feeding and depositing materials in sediments through feces and pseudofeces. This acts to increase water clarity and decrease pelagic phytoplankton biomass. This alteration can correspondingly impact the role of the microbial loop in the food web; for example, they may alter the diversity and abundance of protozoa. In addition, these mussels have negative impacts on native bivalves and alter the community of benthic invertebrates.

Lakes are managed to enhance fish productivity, alter the type of vegetation present, reduce undesirable algae, make water bodies more suitable for boating and/or swimming, and improve water clarity. Many lake management strategies are focused on controlling loading of nutrients into the system. Lake management practices include aeration, biological control, treatment with alum, and treatment with algacides. Management of undesirable biological features may take top down or bottom up approaches. Top down control includes grazer removal by addition of planktivorous fish, while bottom up includes inactivation of P and decreasing external or internal nutrient loading. Species-specific lake management, such as control of a specific undesirable cyanobacterium via cyanophages, is an emerging area.

Streams and Rivers

Properties of Lotic Ecosystems

Lotic systems (streams and rivers) are characterized by water with a unidirectional flow and are classified based on “size” as represented by stream order. Essentially, as illustrated in Fig. 4, the joining of two first order streams creates a second order stream,

Fig. 4 Schematic illustrating manner in which stream order is determined. Arrows represent direction of water flow.

the joining of two second order streams creates a third order and so on. The processes at any site along the system are greatly influenced by upstream processes, as described, for example, in the River Continuum Concept (RCC), as well as by processes in the watershed. Water movement imposes a persistent and critical force on the biota increasing the importance of the benthos of the ecosystem and limiting stratification in contrast to what is typically the case in lakes.

The RCC illustrates the upstream-downstream connection and the role that riparian vegetation structure can play. Although streams in nature may not follow the RCC model, because of human alterations, like reservoirs, and other factors, the notion of this profound connectivity among parts, longitudinal changes, and gradients of biological processes are conveyed by the model.

In addition to the longitudinal and lateral connections, there are vertical connections with streams and the underlying water in a zone called the hyporheos. The extent of the hyporheos varies based on geomorphology and other features. A unique fauna can develop in these areas, in addition to communities of organisms that live in both the surface and the sub-surface. Biofilms formed in the interstitial spaces can be a potent site for microbial activity and create additional niches for microorganisms. Hyporheic processes depend on the redox potential of the surface and underlying waters and the occurrence of anaerobic hyporheic zones in proximity to aerobic surface substrates can create conditions in a relatively narrow spatial scale for a variety of oxidation and reduction reactions. The occurrence of upwelling and downwelling areas as well as whether the hyporheic water is oxic or anoxic determine the biogeochemistry of the system.

In temperate streams, autumnal leaf inputs are a major source of organic matter for the food web. The quality of this leaf material as a biological resource varies among species based on structural properties and chemical constituents. These leaf materials are conditioned by microorganisms, especially bacteria and aquatic hyphomycetes, and can then be consumed by macroinvertebrates, functionally defined as shredders (Fig. 5). The fecal production and fragmentation resulting from the feeding of these invertebrates results in the generation of fine particulate organic matter (FPOM). This FPOM is then available to another functional group of invertebrates, the collectors.

Fig. 5 Decomposition of leaf material in a stream depicting microbial colonization, consumption by macroinvertebrates shredders, and generation of fine particulate organic matter. Reproduced from Nikaido, H., 2003. Molecular basis of bacterial outer membrane permeability revisited. *Microbiology and Molecular Biology Reviews* 67, 593–656.

Disturbance via flooding is another major feature of streams that can have varying impacts on the biota depending on the seasonality, magnitude and duration of the event. Stream life is adapted to the flowing water conditions, but water velocity and depth drastically increase during flooding causing organisms to be dislodged. In addition, benthic materials can be entrained in the water column and be transported resulting in scouring of surfaces and loss of biofilm. Flooding also connects the stream proper to its floodplain and the input of allochthonous materials jumps (including microorganisms, nutrients and organic compounds).

Overall, lotic ecosystems features that are critical to microbial ecology are:

- The unidirectional flow of water.
- The high degree of mixing resulting in a lack of stratification and high aeration.
- Strong interconnection to the surrounding watershed and terrestrial environments.
- Important role of the benthos as a habitat for microorganisms and site of nutrient uptake.
- The significance of allochthonous inputs of microorganisms, organic compounds, nutrients, and particles.
- Importance to humans as water sources and transporters of waste water.
- Impact of humans on the environment through sewage, industrial pollutants, agricultural run-off, reservoir construction, removal of woody debris, channelization, etc.

Microbial Processes

Food webs and the C cycle

As in other freshwater environments, DOM is the dominant fraction of the detrital pool. DOM is made available to higher trophic levels through the microbial loop (Fig. 6); bacteria utilize the DOM and are in turn consumed by protozoa. Although rates of consumption per individual are much higher for ciliates than flagellates, small flagellates are the predominant protozoan predator of bacteria. Protozoa can then be eaten by meiofauna, such as nematodes or benthic copepods.

Another critical process in the C cycle is degradation of coarse particulate organic matter (CPOM) like leaves and wood. Aquatic hyphomycetes play a central role in degradation of CPOM and can penetrate into the tissue of decomposing leaves facilitating colonization by bacteria. There is evidence of competition as well as of facilitation among bacteria and fungi on leaves decomposing in streams. As noted above, these conditioned leaves are then palatable to leaf shredding invertebrates. There are clear patterns of temporal succession within the microbial community of leaves with some fungal and bacterial species serving as early colonizers and others appearing later in the process.

Conditioning of leaf material by microorganisms facilitates consumption by macroinvertebrates who assimilate various fractions of the microbial: leaf assemblage (Fig. 6). In addition, leaf-eating invertebrates play host to a variety of microorganisms; for example, the caecum of the crane fly larva, *Tipula*, boasts large numbers of bacteria.

The importance of algal production, and thus autochthonous C sources, varies greatly and light limitation is crucial. Both shading from riparian vegetation and turbidity can limit light and restrict algal production. Many low order streams with well developed canopies are considered heterotrophic because the P/R ratios are less than 1. In this case, the food web is dependent on C fixed in the terrestrial environment representing allochthonous sources of organic compounds. In contrast, the RCC predicts at

Fig. 6 Basic illustration of C transfers in a stream where the coarse particulate organic matter is leaves. Reproduced from Nikaido, H., 2003. Molecular basis of bacterial outer membrane permeability revisited. *Microbiology and Molecular Biology Reviews* 67, 593–656.

middle orders the P/R ratio will reach its maximum. The P/R ratio is also expected potentially to be greater than 1 in open canopy streams especially those with abundant nutrients and suitable substrates for algal attachment.

Algal: bacterial coupling, which is widely observed in marine and lentic ecosystems, can also be evident in streams. Although the absolute contribution of autochthonous organic C to the overall DOC pool may be limited, this fraction generally has higher lability than the allochthonous fraction. The contribution of breakdown products of plant structural materials (lignocellulose) to the allochthonous fraction is high and these products can be highly recalcitrant. The basis for the observed algal:bacterial coupling has two components: growth of bacteria on algal released organic compounds and use of the algal cells as a physical substrate for attachment.

Although the role of viruses in streams is largely unexplored, they potentially can alter C flow through the microbial loop by attacking bacteria and other organisms. Clearly, in other aquatic environments bacteriophages can be an important component of the microbial loop, and the abundances of viruses observed in lotic ecosystems, suggests that this is also the case in flowing waters.

N cycle

One characteristic of nutrient relations in streams is the spiraling manner with which nutrients as well as bacterial cells are transported (Fig. 7). The nutrient spiraling concept describes the process by which an atom that is released into the water column travels some distance downstream before being taken up again. The spiraling length varies depending on many stream properties such as retentiveness of the channel and water velocity. Transport of nutrients in this manner is experimentally evaluated by measuring the uptake length of material released into the water column.

In addition to biological processes, geochemical processes impact N dynamics in lotic ecosystems. Reactive sites in the benthos can result in chemical transformation and sorption of nutrients. This impacts nutrient availability to the biota, as well as transport downstream.

Nitrogen, in particular, has been the subject of numerous studies in stream ecology because of its potential to serve as a limiting nutrient, influxes of N from fertilizer, and role in water quality. The quantity of N is highly variable among streams based on influxes from outside sources and biological processes in the riparian zone. Both assimilatory and dissimilatory reactions occur in the N cycle in streams and the role of particular N transformations is variable. Both inorganic and organic N are important N cycle participants, although most emphasis has been placed on inorganic N.

Sorption of ammonium to sediments can be high and, correspondingly, ammonium concentrations in water of rivers and streams tends to be low. The benthos creates circumstances in which ammonification, denitrification and nitrification can take place within a comparatively narrow fraction of the benthos and there can be steep redox potential gradients (Fig. 8). Depending on the redox potential, the hyporheos can be potent sites of denitrification. Denitrification in the soil of the riparian zone can also contribute to the stream N cycle.

N enters streams from both upstream, terrestrial and groundwater sources where it is subjected to various microbial transformations (Fig. 9). Processes are dominated by benthic components and are highly dependent on the oxygen gradient within the sediment.

P cycle

Phosphorous in aquatic ecosystems is often a limiting nutrient and the form of P greatly impacts biological activity. Often soluble reactive phosphate is measured and represents a readily assimilated form; dissolved organic P is also present but is used more slowly. Sorption and desorption of phosphate to sediments (particularly fine particles acts to control the concentration of inorganic P in the water in streams and rivers. In addition, P concentrations can increase greatly after flooding especially with input from runoff or sewage.

Fig. 7 Schematic illustrating the manner in which cells and chemical compounds are transported some distance downstream before uptake into the benthos (via attachment, sorption, biological assimilation, etc.). Materials are subsequently released creating a spiral-like pattern. Reproduced from Nikaido, H., 2003. Molecular basis of bacterial outer membrane permeability revisited. *Microbiology and Molecular Biology Reviews* 67, 593–656.

Fig. 8 Interplay between aerobic and anaerobic zones and N transformations in the benthos of a stream.

Fig. 9 Schematic of the nitrogen cycle in a stream.

Microbial Communities

Microbial communities in streams are a complex mixture of cells from allochthonous locations and those produced within the stream proper. Distinguishing amongst these components is quite problematic and the relative contribution of the fractions depends greatly on local events, such as rainfall, flooding, etc.

Biofilms with complex 3-dimensional structures form on stream surfaces including wood, leaves, rocks, and smaller particles. These biofilms are critical habitats for microbial production in lotic ecosystems and consist of complex mixtures of cells of different types embedded in a matrix of extracellular polysaccharide. The matrix is interspersed with channels serving as transport venues and plays host to a mixture of autotrophic and heterotrophic microorganisms. Water velocity is a major determinant of biofilm thickness in streams and physical disruption can “reset” the community by clearing the surface of many of biofilm residents.

The nature and activity of the biofilm may vary depending on substrate type and various terms are applied to biofilms on different surfaces, such as epilithon for biofilms on rocks, epiphyton for biofilms on macrophytes, and epixylon for biofilms on wood. Within the biofilm, various niches occur and there are opportunities for many types of biotic interactions, such as predation and competition. The biofilm creates an opportunity for cells to maintain position in the flowing water and to accumulate resources in transport. Of particular importance is the ability of the biofilm to aide in retention of enzymes released from the cells to degrade polymers.

Activity of enzymes in biofilms and other habitats, including phenol oxidase beta -D-glucosidase phosphatases, endocellulase, cellobiohydrolase and aminopeptidase, has often been measured to assess the potential for enzymatic degradation. Typically, assays rely on chromogenic or fluorogenic substrates. Although these methods do not allow the researcher to determine the organism that produced the enzyme, they do provide measures of specific activity and degradative potentials.

Like nutrients, microbial cells are also transported along the length of the stream; this process is described in the information spiraling concept. A variety of processes influence release of cells from surfaces, including the activities of animals, physical disruption, sloughing, and natural dispersal properties of the species. The uptake length of bacterial cells has been measured in streams through experimental addition of bacteria.

Bacterial communities in streams, as in lakes, are numerically dominated by *Proteobacteria*, particularly the Beta-*Proteobacteria*. Although the diversity of bacteria in streams and rivers is less studied than marine or lake environments, we do know that the *Proteobacteria*, *Actinobacteria*, and *Cytophaga-Flavobacterium* cluster are common in lotic ecosystems. Some bacterial groups may perform specialized roles in nutrient cycling or in degradation of particular organic compounds. For example, the actinomycetes participate in the decomposition of leaf material in streams along with other types of bacteria and the hyphomycetes. Based on meta-analysis of several studies, water temperature, hydrology, organic matter and nutrients are seasonally predictable and correlated with microbial diversity.

Although there is increasingly good data that describes the bacterial community composition in streams, there are still limitations in our ability to connect structure and function. In streams and rivers (as well as other freshwater habitats), the number of bacterial cells in the community that are active (such as those that are undergoing respiration) is often a small percentage of the total number of cells. This may be a particularly important component in lotic ecosystems because of the inputs of large numbers of allochthonous cells. Although these cells are not contributing necessarily to ecological functions, they are still detected via many of the widely used methods.

The contribution of archaea to lotic ecosystems is largely unknown beyond the role of methanogens. Relative to bacteria and other systems, there is very limited information about the abundance, diversity and activity of Archaea in streams and rivers.

Fungal communities in streams, as well as other freshwater environments, are dominated by aquatic hyphomycetes which are identified based on the structure of their conidia. Hyphomycetes are not a specific taxonomic group; rather they are a heterogeneous group of fungi. Hyphomycetes are one type of microsporidic fungi and produce conidia directly from hyphae or via conidiophores. The group can be further subdivided and, in streams, much focus is on the so-called aquatic hyphomycetes, a polyphyletic group, that play an established role in decomposition of leaf material. Common genera of hyphomycetes found include: *Anguillospora*, *Tetrachaeum*, *Tetracladium*, *Clavatospora*, *Goniopila*, *Helicromyces*, *Lemonniera*, and *Heliscella*.

Algal communities in streams can be light limited (either by shading of riparian vegetation or turbidity) and nutrient limited and their contribution to the C in streams varies based on these limitations. Attachment to surfaces is another critical need as phytoplankton generally develops only in large rivers. Diatoms are both diverse and abundant in streams particularly attached to rocks and cobbles and are generally the most abundant algae in stream biofilms. The distribution of diatom species varies predictably among locations with different water velocities. In addition, the growth form of filamentous green algae (i.e., *Cladophora*) varies with velocity.

Algal stream communities are greatly impacted by light, temperature, herbivory, water velocity, substrate type and by nutrient availability. This latter includes silica which is essential for diatoms, however, in lotic ecosystems silica is generally found in adequate supplies. Diatoms, which include genera such as *Achnanthes*, *Gomphonema*, and *Navicula*, can be more successful under low light conditions than other algae; this is a likely contributor to their success in streams. In terms of nutrient limitations, autotrophs in streams are generally thought to be P limited not N (although exceptions to this trend occur).

Protozoa in streams are in many ways less well studied than in lakes. It is known that protozoa play a major role in the microbial loop in streams. Small flagellates are considered to be the most important consumers amongst the protozoa in streams and can greatly alter bacterial abundance.

Anthropogenic Disturbance

Human impact on streams is profound and has greatly altered the structure and function of streams and rivers globally. These impacts in turn influence the role of the microbial community and essential biogeochemical processes.

Introduction of sewage effluent and fecal waste from human/animal activities into lotic systems is widespread and serves as a source of microorganisms, nutrients, organic compounds, as well as various pollutants used by humans and disposed of in sewage. The input of allochthonous microorganisms in this manner has critical impacts on water quality, human health, and the spread of water borne diseases. Inputs of organic compounds and nutrients from sewage alter the resource availability to the biota and can, in some cases, result in reduction of oxygen concentrations in the water. Often these inputs are monitored using biological indicators of sewage contamination such as enumerating fecal coliforms. In addition, other fecal-associated organisms and viruses may be monitored to assess different types of risks (like *Cryptosporidium* from cattle feces) or fecal streptococci (Gram positive cocci) from human sewage effluent. To reduce the risk of contamination of water by pathogens, treatment of effluent is often done, in particular using chlorination. Chlorination does have associated health risks through the production of trichloromethanes from natural occurring dissolved organic compounds and alternative strategies and dechlorination can be used to minimize these risks.

An area of emerging concern is the presence of personal care products, such as pharmaceuticals, in streams arising from wastewater effluent. Such compounds have been detected in a variety of streams and have an unknown impact on the microbial community. For example, the presence of antibiotics may promote occurrence of antibiotic resistance genes.

Humans also alter the physical structure of streams through channelization for navigation purposes, removal of woody debris, straightening of channels and removing of meanders, dam and reservoir construction, etc. Such impacts have gone on for many years and thus have had long term consequences on stream and river function. In particular, water residence time is altered by these activities that, in turn, alters transport of materials and uptake lengths. For some alterations, like addition of reservoirs, residence time is greatly increased creating unexpected lentic regions in the middle of otherwise “normal” river continua. At these discontinuities, material in transport can drop out of the water column and pelagic processes can replace benthic processes in relative importance.

Acid mine drainage represents one specific impact on streams and has huge impacts on the microbial ecology of the system. The problems start with the mining of coal that is mixed with pyrite. Iron and sulfur oxidation leads to a decrease in pH and favors the growth of specific types of microorganisms which maintain the low pH. This greatly lower pH has profound negative impacts on all other forms of stream life.

Comparison Among Freshwater Habitats

Hydrology, the potential for oxygen depletion, whether organic C is primarily of allochthonous or autochthonous origin, and the role of plant detritus are among the major determinants of variations among freshwater ecosystems in microbial processes. These variations couple with the relatively small number of studies on some aspects of ecology of microorganisms in freshwater habitats limits the number of generalities that have emerged.

A critical limitation on our ability to draw generalities about microbial ecology of freshwater habitats is the relatively limited number of studies performed on certain aspects of the topic. This fact coupled with the limited coverage of the broad range of diversity of ecosystems suggests that we have yet to reveal many of the underlying tendencies that may unite freshwater habitats. It is not known if specific locations that have been studied in some detail are representative of the greater array of locations that have never been studied.

Overall, major determinants of the structure and function of the microbial community in freshwater habitats are the occurrence and importance of plant detritus, the nature of the hydrology of the system, and the occurrence of oxic and anoxic zones. The potential for drastic spatial and temporal changes in critical factors, such as redox potential, creates opportunities for a diversity of different microbial niches and interconnectivities. This creates interesting spatio-temporal juxtapositions of complementary microbial processes over comparatively small scales. Each microbe-mediated process can be altered by anthropogenic disturbances, which are all too common in freshwater systems because of the proximity to human populations, strong connections to the surrounding landscape, and vital importance for human success.

Emerging Directions and Approaches

Molecular methods are key to the future of freshwater microbial ecology. However, there are limiting factors that will be overcome with time including the need for more sequence data from a wide range of freshwater habitats, meta analysis of these data sets, new pipelines for sequencing, etc. In addition, knowledge of understudied and uncultured organisms is needed to make sure that all taxa are well covered. Perhaps the biggest challenge is to attribute specific functional abilities to specific taxa.

Advances in freshwater ecology also have the potential to enhance our understanding of their role as habitats for microorganisms. More specifically the use of embedded wireless sensors has the ability to measure and transmit critical environmental data, like temperature and dissolved oxygen, in real time. Sensor platforms or small single sensors placed in freshwater systems are becoming an increasingly important tool for monitoring of environmental conditions; real time monitoring has become increasingly prevalent in marine systems over the past several years.

Beyond this capacity to measure physical and chemical conditions of the environment, sensor technology can also be used to detect specific microorganisms or their products. For example, there are sensors for fluorometric detection of specific pigments of cyanobacteria, such as phycocyanin, which have application in monitoring of harmful algal blooms as well as those for more general compounds, like chlorophyll. There is also technology now that allows detection of specific bacteria (such as *Escherichia coli*) and may rely on antibody based detection, for example. The next generation of biosensors which is just now being developed for and applied to freshwater systems are nucleic acid-based systems which can be targeted to detect a variety of bacteria and viruses.

Ultimately, the integration and analysis of many large data sets whether they be 'omics' or environmental data from sensors will continue to be important in the future. In this way, discrete findings from individual studies can be compared and built upon in search of generalities.

Topic 1: Systems Biology as Genome-Scale Science

Some 60 years ago, the promise of molecular biology held that if we knew and understood the function of the molecules that comprise cells, then we could understand cells and their functions. Although this was true in principle, the sheer number of molecules made it very difficult to comprehend so many simultaneous functions. Thus, to fulfill this promise, systems analysis is needed.

The simultaneous measurement of members of whole classes of biomolecules became possible over the past two decades (metabolomics, lipidomics, proteomics, etc.). In addition, methods (ChIP-Exo, Ribo-Seq, PPI, etc.) have been developed to measure interactions between large numbers of biomolecules. Consequently, there are a growing number of datasets available that give us the molecular composition of cells under a certain condition. Many of the chemical interactions (i.e., mechanisms) between many of these components are now known and this knowledge gives rise to reconstructed biochemical reaction networks on a genome-scale that underlie various cellular functions. Structured representations of this information can be converted into a mathematical form enabling computation and model building. Thus the formulation of '*in silico*' cells became possible that represent their *in vivo* counterpart based on our current state of knowledge. *In silico* cells became a foundation of the bottom-up approach to systems biology.

Systems biology is not focused so much on the biomolecules themselves, but rather on the activity of the links (i.e., their chemical and physical interactions) that connect them, and the computation of 'functional states' of reconstructed networks. Functional states of networks correspond to observable physiological or homeostatic states. Completing quantitative relationships between the chemical components of a cell (with their genetic bases) and their physiological functions is the promise of (molecular) systems biology. This undertaking represents the *de facto* construction of a high-dimensional, mechanistic genotype–phenotype relationship.

As an example of the systems biology approach, we illustrate computational prediction of essential genes, and synthetically lethal gene pairs, based on genome-scale metabolic models. Predictions of gene essentiality are made by computing the growth capabilities (i.e. the synthesis of all biomass components in the right ratios) of an *in silico* cell by removing the activities of a single gene. Synthetic lethals can be predicted by simultaneously removing two genes from an *in silico* cell and computing its growth capabilities. These predictions represent perhaps the largest scale and most intricate computational predictions of phenotypes performed to date, reaching hundreds of thousands of predicted experimental outcomes. The comparison of computed lethality and experimental measurement in a number of studies is shown in Fig. 1. The remainder of this article illustrates the concept of a network reconstruction, the formation of an *in silico* cell (i.e., a computable knowledge base), and its uses to understand biological functions.

Fig. 1 Predicting experimental outcomes of cellular growth screens. The number of predictions made on growth screens that cross environmental conditions with gene knockouts has grown steadily over the past 15 years. Over this time, both single-gene knockout (SKO) predictions (red line) and double-gene knockout (DKO) predictions (blue line) have become increasingly accurate. Figure is taken from Monk, J., Palsson, B.O., 2014. Predicting microbial growth. *Science* 344, 1448–1449.

Fig. 2 The conceptual basis of constraint-based modeling. With no constraints, the flux distribution of a biological network may lie at any point in a solution space. When mass balance constraints ($Sv=0$) imposed by the stoichiometric matrix S (labeled 1) and capacity constraints imposed by the lower and upper bounds (a_i and b_i) (labeled 2) are applied to a network, it defines an allowable solution space. The network may acquire any flux distribution within this space, but points outside this space are denied by the constraints. Through optimization of an objective function, one can identify an optimal flux distribution that lies on the edge of the allowable solution space. Figure is taken from Orth, J.D., Thiele, I., Palsson, B.Ø., 2010. What is flux balance analysis? *Nat. Biotechnol.* 28, 245–248.

Topic 2: Introduction to COBRA Methods and Reconstruction

Two fundamental steps: The underlying CONstraint-Based Reconstruction and Analysis (COBRA) methods are based on relatively simple concepts, but their application can result in non-intuitive, novel predictions. COBRA entails two fundamental steps (Fig. 2):

- The first step is the network reconstruction process described above. A reconstruction, once mathematically represented, can distinguish between the possible and impossible phenotypic states. Basically, one can find the fundamental constraints that come with all the interactions between the biomolecular components of a cell and form what is called a ‘solution space.’ This space contains all the allowable network states. It is analogous to the term ‘reaction norm’ used in ecology and genetics.
- The second step is to find the states within the solution space that are likely to represent the homeostatic state of an organism. These states are found by using constraint-based optimization methods. Optimization requires an objective function that describes the desirable properties of the homeostatic state. Constraint-based optimization finds the best points within the solution space based on the stated objective function. The most commonly used objective function is growth rate, although many others have been studied. Ultimately, the objective function describes distal causation, thus representing fundamental biological causation.

Illustrative example: An overview of the COBRA method is shown in Fig. 3 for a simple toy network, though the same procedure is used to produce COBRA models at the genome scale. The key differences being the number of reactions in the model and a few additional considerations, which will be discussed below in Topic 3.

A COBRA model for the simple toy network shown in Fig. 3 can be constructed using the following steps. First, the stoichiometries for all of the reactions in the toy network must be defined including all possible inputs (b_1) and all outputs (b_2 and b_3) of the system. This definition is trivial for the toy network shown, but when executing this process on a genome scale, there are numerous additional considerations that must be addressed. Next, the catalog of reactions must be transformed into a mathematical format that lends itself to computation. This transformation is accomplished by constructing what is called a stoichiometric matrix, shown in Fig. 3. In this format, each column represents a unique reaction and each row a unique metabolite. The numbers in the matrix thus indicate the stoichiometry of the metabolite in each reaction, with negative numbers representing reactants, and positive numbers representing products. The matrix entry is 0 if the metabolite does not participate in the reaction.

Constructing the stoichiometric matrix alone does not produce a useful COBRA model. Bounds must be placed on the activity of each individual reaction as well. Bounds provide the limits on the amount of flux each reaction can carry. In the toy example the units of the reaction flux is ambiguous, but at the genome scale reaction fluxes have units of mmol per gram dry weight of cell per hour ($\text{mmol gDW}^{-1} \text{hr}^{-1}$). In the toy example, all reactions are irreversible and operate only in the forward direction, indicated by reaction bounds being greater than or equal to 0 for each reaction. If reactions operate only in the reverse direction or are reversible, the lower reaction bounds should be set below zero. Reaction b_1 defines the input of species into the system, which is metabolite A in the toy network, and is limited to 10 units of uptake flux (Fig. 3). This flux limitation is analogous to the substrate uptake rate for an organism’s genome-scale model.

After defining the stoichiometric matrix and reaction bound constraints, we can define a particular reaction to optimize (i.e., maximize or minimize its reaction rate, or flux) subject to the constraints inherent in the model. One of the several freely available software tools can then be used to compute with the model using a linear programming solver. Solutions to a COBRA metabolic model are non-unique, meaning there are an infinite number of flux states that can produce an optimal result. The full extent of fluxes that satisfy constraints can be represented as a solution space, depicted as the polygon for the toy network in Fig. 3. This example shows all of the fluxes possible through reactions b_2 and b_3 given the stoichiometric and reaction bound constraints of the toy network. Two extremes of the solution space are shown. These are equally optimal solutions that produce a maximum amount of flux through the b_2 reaction.

Metabolic Network

Constraints

	Stoichiometry									Reaction Bounds		
	v ₁	v ₂	v ₃	v ₄	v ₅	v ₆	b ₁	b ₂	b ₃	Lower Bound	Reaction	Upper Bound
A	-2	0	0	0	0	0	2	0	0	0	v ₁	100
B	2	-2	-2	0	0	0	0	0	0	0	v ₂	100

										0	b ₃	100

Optimize for b₂

Fluxes Satisfying Constraints

Fig. 3 Overview of the constraint-based modeling method. The toy metabolic network displayed in the top panel can be simulated by converting it into a mathematical format, as shown in second panel. Doing so involves first converting the stoichiometry of all of the reactions in the network into a matrix representation where the columns correspond to reactions, the rows correspond to metabolites, and the matrix values correspond to the stoichiometry of the metabolite in the reaction. Further, the upper and lower flux limits on each reaction must be defined as reaction bounds, as shown. This representation can be converted into a linear programming problem using available software and solved. The solution to this problem however is not unique, and the full range of possible solutions can be represented as a solution space, shown in the third panel. Two of the labeled vertices of the solution space are shown overlaid on the network in the bottom panel which are equally optimal solutions that give the most reaction flux through b₂. These can be considered low byproduct and high byproduct solutions based on the amount of metabolite byp secreted.

Escherichia coli as a model organism for systems biology: The organism with the most extensive, validated, and widely-used COBRA model is *E. coli*. As a model organism, many metabolic processes were first discovered in *E. coli* and are best characterized in this organism. This rich *E. coli* bibliome has culminated in the recent, most comprehensive COBRA model of *E. coli* K-12 MG1655, iML1515. Information regarding the pathways and processes modeled in iML1515 and other high-quality models can be found at bigg.ucsd.edu.

Scalability: From a strain to a species to infections on a national scale: Beyond predicted metabolic capabilities of the lab strain, the *E. coli* K-12 MG1655 model can help us understand the *E. coli* species as a whole. An initial study of 55 sequenced *E. coli* strains demonstrated the ability to predict auxotrophies and niche-specific nutritional requirements (Monk et al., 2013), that were subsequently repeated with over 1200 strains (Monk et al., 2017).

Fig. 4 Increase in sequenced genomes for five common clinical pathogens. If current trends are maintained, the number of sequenced genomes for all five pathogens will equal the number of infections per year by 2021. The number of sequenced genomes per organism were obtained from the Patric database (www.patricbrc.org). The infections per year were obtained from the Center for Disease Control (www.cdc.gov) with the infections per year obtained for *S. aureus* from the Pew Charitable Trusts (www.pewtrusts.org). Figure prepared by Jonathan Monk.

Prediction from sequence alone opens up new possibilities. For example, using a genome sequence of a clinical isolate, iML1515 can be used to construct COBRA models tailored to that specific pathogen. With the number of sequenced clinical *E. coli* isolates, and those of other major pathogens, increasing at a staggering pace (Fig. 4), genome-scale models offer a means to extract essential information that might lead to guidelines on how to treat a specific unique infection. If such predictions materialize, we can move the field of infectious disease closer to truly personalized medicine. If the current rate of sequencing continues, it becomes feasible by ca. 2021 to sequence all clinical isolates in the United States (Fig. 4). A truly amazing prospect.

Topic 3: The Metabolic Requirements for the Production of Biosynthetic Precursors

Pathway versus genome-scale networks viewpoints: Traditionally, microbiology is taught from a pathway or biochemical reaction perspective. In reality, however, cellular survival relies on the activity of many such interconnecting pathways working in conjunction to produce the metabolites needed for growth in the proper amounts. Beyond this, these individual pathways vary among species and even to some extent within strains of the *E. coli* species itself. Obtaining actionable knowledge by mapping out the metabolic pathways within an organism is difficult. To this end, systems biology methods provide the tools that enable the use of this information to compute phenotypic and metabolic characteristics of an organism despite the complex reality of cellular metabolism.

The power of systems biology can be illustrated by analyzing a 11 reaction linear pathway to produce L-histidine from D-ribose. It is shown in Fig. 5 as it might be discussed in a traditional microbiology book or class. What is typically glossed over, however, is the role that cofactor or metabolic precursor availability may play in shaping the functioning of this pathway or how the activity of any byproducts that are synthesized may affect other metabolic activities in the cell. When using flux balance analysis to simulate the production of L-histidine from D-ribose aerobically (oxygen uptake limit of $10 \text{ mmol gDW}^{-1} \text{ hr}^{-1}$), 72 total reactions must be active in order to enable the function of the 11 reaction pathway in a fully mass balanced way.

Why are these 61 extra reactions necessary? L-histidine synthesis is an anabolic process relying on chemical or energetic contributions from various metabolites in the cell. For three reactions in the pathway energy from ATP is required to fuel metabolic conversions or to transfer high energy phosphate bonds to L-histidine precursors to fuel future metabolic conversions. Synthesizing ATP thus requires that some of the substrate (D-ribose) is diverted from reactions in the L-histidine synthesis pathway to the pentose phosphate pathway and, eventually, to glycolysis. Flux through glycolysis enables ATP synthesis directly as a product of glycolytic reactions and indirectly by reducing NAD^+ to NADH, which can be used for oxidative phosphorylation. Some additional ATP in this example is produced by fermentation and acetate secretion due to the limit on oxygen uptake being set to $10 \text{ mmol gDW}^{-1} \text{ hr}^{-1}$. This value is below the amount needed for oxygen excess and fully aerobic metabolism in the simulation. Further, L-histidine contains three nitrogen atoms that it must acquire given that D-ribose does not contain nitrogen. One nitrogen is incorporated from adenosine and the other two are added from L-glutamine and L-glutamate. The pathways that incorporate inorganic nitrogen into these metabolites must therefore be active. Side products of the L-histidine synthesis pathway must also be degraded. One such byproduct is 5-amino-1-(5-phospho-D-ribosyl)imidazole-4-carboxamide (AICAR) which is

Fig. 5 Contrasting the traditional pathway view (i.e., textbook) and the network view (i.e., systems biology) of the biochemical processes needed to produce a single biosynthetic precursor. The L-histidine biosynthetic pathway is considered 'long', being composed of 9 enzyme-catalyzed reactions on 1 operon. When considering L-histidine synthesis from D-ribose, 2 additional reactions are required to phosphorylate D-ribose to form 5-Phospho-alpha-D-ribose 1-diphosphate (PRPP) so that it can enter the L-histidine biosynthetic pathway. This brings the total number of reactions in this example pathway to 11. In order to synthesize L-histidine from D-ribose in a way that is fully mass-balanced, however, it can be seen that a total of 72 reactions (61 of which are enzymatic) are required. Below we discuss the full metabolic requirement for such biosynthesis.

degraded to ADP in this example, though *in vivo* AICAR is used for inosine biosynthesis. Lastly, all NAD^+/NADH cofactor usage must be balanced, meaning that NADH must be produced and consumed at equal levels (Fig. 5). Synchronizing all these functions requires a total of 61 additional active biochemical reactions.

Networks are highly interconnected, and thus their characteristics can be non-intuitive: Many important properties of the network cannot be determined based on simple characteristics or intuition. For instance, there is little relationship between the predicted carbon yield (i.e. the fraction of carbons in a substrate that end up in the product metabolite) and the number of reactions separating the substrate and product metabolite (Fig. 6). D-ribose, D-glucose, and other metabolites with few enzymatic reactions separating them from L-histidine are actually capable of synthesizing L-histidine with a carbon yield similar to substrates separated from L-histidine by many more intermediate reactions, like acetate.

Acetate, however, is a poor-quality substrate for *E. coli*, meaning that cells grow slowly when fed this metabolite as a carbon source. This is due to the fact that growth is dependent on the organism's ability to produce all biosynthetic precursors and energy

Fig. 6 Maximal aerobic (oxygen uptake limit of $10 \text{ mmol gDW}^{-1} \text{ hr}^{-1}$) carbon yield of L-histidine from 15 *E. coli* carbon substrates. The number of active reactions required for each substrate to produce L-histidine is shown above each bar.

necessary to grow from the *in silico* growth media. Therefore, while acetate may be able to produce L-histidine efficiently, it is a highly oxidized carbon source meaning that it cannot produce ATP as efficiently as substrates like glucose, limiting its growth capabilities.

From a single amino acid to synthesis of all biomass constituents: This systems-level analysis has shown that even the activity of a short, linear pathway relies on the interconnectivity of many different metabolic subsystems in order to operate. Beyond this, all of the considerations discussed for the L-histidine biosynthesis pathway hold true for all other essential biosynthetic precursors that need to be synthesized in a growing cell. For an organism to successfully synthesize the dozens of macromolecular precursors and produce the amount of energy needed to grow, all of these pathways must be active and working in harmony.

In order to take the biosynthesis of these biomass constituents into account, COBRA models include a reaction called the biomass objective function. This function includes all of the essential metabolites (i.e., structural components, biomass building blocks, cofactors and currency metabolites, etc.) with empirically derived coefficients corresponding to their concentrations in a growing cell. The flux through this reaction corresponds to the *in silico* growth rate of the cell under the environmental conditions imposed. Since the production of each metabolite in the biomass objective function must be produced in the proper amounts and in a fully mass balanced way, the interconnectivity of the pathways producing each essential metabolite can be fully accessed in a model simulation. Remarkably, the power of systems science allows us to perform these computations.

Topic 4: The Proteomic Requirements for the Production of Biosynthetic Precursors

Proteome size is limited: The availability of protein within a growing cell is limited to about 2–3 million protein molecules per cell. Cells have therefore evolved to utilize the available proteome as efficiently as possible. This optimization of proteome investment has led to certain unintuitive and sometimes seemingly “wasteful” growth phenotypes (e.g., acetate overflow in *E. coli* or the Warburg effect in cancer cells) that require the consideration of protein cost to be accurately described and understood. While the COBRA methods described in Topics 2 and 3 have proven effective in computing the metabolic potential and characteristics of an organism, they do not account for protein costs. In other words, metabolic network models do not consider the proteome investment required to synthesize the enzymes that catalyze flux through a metabolic network.

This lack of consideration of proteome cost means that any two pathways converting metabolite *A* to metabolite *D* are treated equally by the model regardless of the efficiency of the enzymes catalyzing the reactions, the length of the pathways, or the metabolic investment required to synthesize the enzymes making the metabolic conversions. Using an economic analogy, the ‘operating expense’ of a metabolic reaction is accounted for in a metabolic model but not the ‘capital expense’ required to build the protein that catalyzes the reaction. Ignoring proteome costs can lead to metabolic model predictions of incorrect or unrealistic pathway activity and the presence of alternative optimal reaction flux states (Fig. 3).

Genome-scale models can compute proteome composition: COBRA models have been developed that explicitly describe the processes involved in gene expression and proteome synthesis. These genome-scale models of proteome synthesis impose a biosynthetic cost of catalyzing a metabolic reaction in the model by requiring the synthesis of the catalyzing enzyme in order for a reaction to carry flux. They are called ME-models, for Metabolism and Expression.

The proteome cost is imposed by considering the dilution of macromolecules to daughter cells as the organism grows and divides (Fig. 7(A)). The faster the cell is growing, the more the macromolecules are passed on and therefore must be replaced through model synthesis. This relationship provides the basis for genome-scale models of proteome synthesis (ME-models) and

Fig. 7 (A). A depiction of each of the major cellular processes involved in gene expression, all of which are modeled in gene expression models. (B). In order for a single genome-scale model of proteome synthesis (ME-model) to solve, multiple processes involved in cellular growth must be reconciled. For example, the cellular reaction flux state must be supported by the proteome catalyzing all of these processes. The proteome, in turn, is itself supported by the synthesis of biomass precursors. The biomass precursor demand for the proteome then informs the optimal metabolic flux state. Solutions of ME-models can then be validated against disparate OMICS data types (i.e., ^{13}C fluxomics, proteomics, etc.). Panel (A) is from Lloyd, C.J., Ebrahim, A., Yang, L., et al., 2017. COBRAme: A computational framework for building and manipulating models of metabolism and gene expression. bioRxiv.

their ability to link the synthesis of a macromolecule to the reaction which it catalyzes. For a more thorough explanation on this computational method, refer to Lloyd et al. (2017) and O'Brien et al. (2013).

Proteome limitations lead to optimal proteome allocation that can be a governing constraint: How do ME-models improve the framework we introduced in Topic 2? First, the nutrient uptake and metabolic reaction fluxes are determined by optimal protein utilization as a consequence of limited proteome availability. As opposed to COBRA models of metabolism which require measured substrate uptake rates in order to make feasible predictions, ME-models are capable of determining the optimal nutrient uptake rates with reasonable accuracy. In addition, ME-model solutions more accurately estimate the metabolic flux distribution by eliminating biologically infeasible, alternative optimal flux distributions (described in Topic 2) that do not satisfy the constraint imposed from limited proteome availability. As a result, the optimal solution of a ME-model is effectively unique. Second, the relative abundance of proteins and other macromolecules required to support the metabolic phenotype is predicted by a ME-model. These macromolecule abundances provide novel predictions of macromolecular expression that can be compared against proteomics data or other numerous OMICS data types (Fig. 7(B)). The unique predictions enabled by ME-models open entirely new avenues of biological questions and discovery.

Topic 5: The Condition-Dependent Proteome

The genome-scale computation of the composition of the proteome is just the first step in computationally representing a functioning proteome. To become functional, many proteins require post-translational modification and engraftment of prosthetic groups. Additionally, there are constant degradative forces operating on a proteome. Remarkably, with the chemical basis for these functions, they can be explicitly reconstructed and added to ME-models that compute the composition of the proteome. Here we briefly describe how such *in silico* models of whole cells deal with, (1) the requirement of iron in the functional center of certain enzymes, and (2) the requirement of chaperones to keep the proteome correctly folded in the face of thermally caused protein misfolding.

- (1) *Functionalizing the proteome: metalloproteins.* The catalytic activity of inorganic iron has played a central role in facilitating important metabolic processes in organisms dating back to the beginning of life on earth. As a result, many important processes in living cells still depend on the availability of iron in order to function (Fig. 8(A)). Using ME-models, we can predict how reductions in the availability of iron cause the metabolic phenotype of *E. coli* to change. In agreement with experimental observations, decreasing iron availability causes the cell to grow much slower and shift to secreting D-lactate instead of acetate (Fig. 8(B, C)). The predicted causes of this shift is the reduced activity of the metabolic enzymes that have iron in their catalytic site.

Beyond studying growth and metabolism under iron-limited conditions, ME-models have been developed that incorporate damage and repair processes of iron-containing proteins in the presence of oxidative stress. In doing so, these models have the capability to, for instance, correctly predict amino acid auxotrophies in *E. coli* when exposed to elevated oxidative stress in superoxide dismutase mutants (Yang et al., 2017).

Fig. 8 (A) Central carbon metabolism with the reactions catalyzed by iron-containing enzymes in red. (B) *In silico* predictions of relative growth rate and metabolic byproduct secretion when under varying levels of iron limitation. (C) These *in silico* predictions agree with experimental measurements of *E. coli* growing in iron limitation. Parts (B) and (C) are adapted from O'Brien, E.J., Utrilla, J., Palsson, B.O., 2016. Quantification and classification of *E. coli* proteome utilization and unused protein costs across environments. PLoS Comput. Biol. 12, e1004998.

These two examples highlight the importance of accounting for the metallo-proteome when fully modeling cell metabolism. Both the availability of iron and the oxidation load on iron can be described by elementary processes and thus included in an *in silico* model of a cell.

- (2) *The physical integrity of the proteome: proteostasis.* Beyond incorporating vital coenzymes, prosthetic groups or metal ions, proteins must also be properly folded to enable their proper catalytic function. By incorporating chaperone activity into these models we can now compute the systems level consequences of protein unfolding and refolding (proteostasis). To begin to model the protein unfolding response, we must first understand that proteins themselves have intrinsic capabilities to keep their shape. In a recent study, we described how computed properties of individual proteins can determine when they are targeted by the chaperones of *E. coli* (Fig. 9).

How are these protein properties incorporated into genome-scale models? The recently introduced GEM-PRO pipeline (genome-scale models with protein structures) enables the curation and computation of protein sequences and structures within genome-scale models (Fig. 9(A)). Thousands of 3D protein structures are solved experimentally every year, thanks to efforts of structural biologists

Fig. 9 Utilization of protein structural properties within a genome-scale model for the purpose of modeling thermal stress adaptations. (A) The formal integration is termed a “GEM-PRO”, or genome-scale model with protein structures. Enzymatic reactions are mapped to their corresponding protein sequences and structures. (B) Protein-specific properties can be predicted from sequence and structure, and further computed to reflect protein property changes under stress. For example, four parameters are chosen to represent the influence of temperature on the status of the structural proteome. (C) Incorporation of chaperone folding networks adds the proteostasis network response to the model. (D) Simulated growth rates of an integrated model match very closely to measured experimental rates at different temperatures. (E) Proteome allocation of the cell under thermal stress can be inspected to find a dramatic shift towards chaperone production at high temperatures. Figure is adapted from Mih, N., Brunk, E., Chen, K., et al., 2018. ssbio: A python framework for structural systems biology. *Bioinformatics* 34, 2155–2157. And Chen, K., Gao, Y., Mih, N., et al., 2017. Thermosensitivity of growth is determined by chaperone-mediated proteome reallocation. *Proc. Natl. Acad. Sci. USA* 114, 11548–11553.

worldwide and programs such as the Protein Structure Initiative. However, a large gap remains between known structures and the total number of annotated open reading frames within sequenced genomes. Due to this gap, structural information remains incomplete for a number of reasons, such as the protein (membrane proteins are difficult to crystallize) or organism of interest (some organisms are not as well studied). Fortunately, for model organisms such as *E. coli*, we have now reached a point where structural information is available or can reliably be predicted for a large portion of the expressed proteome. This enables what is broadly known as a structural systems biology for genome-scale models.

Once a GEM-PRO has been generated for *E. coli*, we can then predict or compute protein properties as a function of temperature from first principles (Fig. 9(B)). Incorporating two major chaperone systems and their folding networks (Fig. 9(C)) to the ME-model thus allows us to understand how changes in these protein properties affect the systems-level response to changes in temperature. This model, named foldME, thus enables a surprisingly accurate prediction of relative growth rates under different temperatures (Fig. 9(D)). Furthermore, foldME allows us to inspect changes in the production levels of certain proteins (i.e., the cell’s proteome allocation). Under high temperatures, there is a dramatic shift toward the production of chaperones while shifting away from the production of cytoplasmic proteins (Fig. 9(E)).

Thermostability has often been a property studied in the context of individual proteins, or as a global phenotypic response. FoldME exemplifies how incorporating atomic-level information can expand the systems biology paradigm, and it provides an understanding of how a cell balances its protein production and maintenance (folding) machinery under thermal stress.

Topic 6: Multi-Strain Reconstructions Enable Assessment of Strain Variation

Genomic sequences from multiple strains allow us to ponder the definition of a species. As shown in Fig. 4, there has been a staggering increase in the number of sequenced strains of *E. coli*. These sequenced genomes have allowed us to adapt reconstructed COBRA models to inspect variation at both the gene-level (i.e., absent metabolic reactions, which may cause auxotrophies) and at the base-pair level (i.e., changes to a protein sequence and their impact on structure). This sequence data availability brings into focus the question: “what is a strain and what is a species?” A comprehensive comparison of the metabolic capabilities of 55 strains of *E. coli* and *Shigella* revealed that these strains can adapt to catabolize nutrients with alternate pathways (Monk et al., 2013). This result exemplifies how COBRA models provide utility by predicting a strain’s environmental niche. This approach has been applied to

A) Sequence variation by pathway

B) Sequence variation by domain

C)

D) Variation in HisD

Fig. 10 Analyzing strain variation in *E. coli* at multiple levels. (A) Inspecting variation at the pathway level shows that membrane lipid metabolism and a number of amino acid synthesis pathways top the list of average number of changes in their catalyzing enzymes. (B) Incorporating protein domains into the analysis highlights specific domains that display this variation. (C) 976 genes with metabolic functions are conserved across 99% of *E. coli* strains, and this core set also has mutations. The bar chart shows the average number of amino acid mutations in these core genes for 1122 strains of *E. coli*. (D) L-histidine pathways showed high levels of amino acid differences among genes involved. The pie chart represents the percentage of strains that contain unique *hisD* alleles. The *hisD* allele in *E. coli* K-12 MG1655 is present in only 19 (1.7%) of the sequenced strains. Figure is adapted from Monk, J.M., Lloyd, C.J., Brunk, E., et al., 2017. iML1515, a knowledgebase that computes *Escherichia coli* traits. Nat. Biotechnol. 35, 904–908.

characterize differences in industrially relevant strains of *E. coli*, the aquatic bacterium *Shewanella*, *Staphylococcus aureus*, *Leptospira*, and *Pseudomonas putida*.

Structures can provide a template for analyzing sequence variation. However, some pathways are often quite conserved and essential in many organisms. The L-histidine biosynthesis pathway, for instance, is known to be essential across bacteria, fungi, plants, and archaea, and is present in most strains of *E. coli*. As such, differences in this pathway among strains must now be probed at a deeper level to begin to understand what enables the broad diversity seen within a single species. An initial analysis of sequence-level

variation in over 1000 clinical isolates of *E. coli* revealed a large number of alleles (unique variant forms of the protein) for enzymes in L-histidine biosynthesis and a number of other pathways related to amino acid synthesis (Fig. 10(A)). This analysis was then coarse-grained to consider protein domains, which can be thought of as the functional units of proteins. This domain-level analysis indicated that the aldehyde dehydrogenase (ALDH-like) domain has, on average, more variation across all studied strains compared to other domains (Fig. 10(B)). The last enzyme in L-histidine biosynthesis, *hisD*, contains this ALDH-like domain and had one of the highest counts of alleles, as well as the highest number of mutations conferring an allele (Fig. 10(C, D)). The potential for further characterization of these enzymes due to these variations remains, as these are but clues to begin to understand the true relationship between genotype and phenotype.

Closing

The whole genome sequences that appeared in the mid to late 1990s ushered in the genome era for microbiology. The availability of all the genetic elements on a genome sequence, in turn, ushered in the era of microbial systems biology where the simultaneous function of all the gene products is considered. The basic paradigms of microbial systems biology that have solidified over the past 20 years are manifested in two fundamental steps: first in the reconstruction of all the biochemical, genetic, genomic, and structural information available about a target strain in a formalized fashion, called a reconstruction, and second, in the development of a mathematical framework that allows computational interrogation reconstruction properties, with special emphasis on phenotypic traits. These two steps together comprise *de facto* a multivariate mechanistic genotype-phenotype relationship.

To date, metabolic and proteome synthetic networks have been reconstructed and characterized. Currently, protein structures, proteostasis, and stress responses are being reconstructed at the genome scale. We are thus approaching the point in time where we can explicitly compute over 90% of the proteome by mass and directly relate the outcome of such computations to phenotypic functions. These genome-scale models have invaluable utility to predict and guide hypothesis-driven experimental designs from a genome-scale standpoint and to compare properties of different strains.

Glossary

Antifungal drug An antibiotic drug used to prevent or treat fungal infections.

Biofilm A highly organized microbial community typically attached to a substrate and enveloped within a protective matrix of self-produced exopolymeric material.

Biofilm dispersion The process by which some cells detach from the biofilm and become free-floating. Normally it is considered that these cells will disseminate and seed new infectious sites.

Opportunistic pathogen An infectious microorganism that under normal conditions is a commensal or does not normally harm its host, but can cause active infection when in a compromised host.

Quorum sensing A mechanism to detect population density through the use of signal molecules. This allows microorganisms to communicate and coordinate group behavior.

Virulence factor A molecule or property produced by or associated with a pathogen that contributes to the pathogenicity of the organism and its ability to cause infection.

Clinical Significance and Spectrum of Fungal Biofilms

Fungal infections represent an escalating problem affecting an expanding spectrum of immune- and medically-compromised patients (Brown et al., 2012). These infections carry unacceptably high morbidity and mortality rates, due in part to the limited arsenal of antifungal agents, their inherent toxicity, and the emergence of resistance (Ostrosky-Zeichner et al., 2010). One factor that further complicates treatment of fungal infections is the fact that fungi are capable of forming biofilms, which are attached and highly structured communities of cells surrounded by a self-produced exopolymeric matrix (Ramage et al., 2009). It is now well established that biofilms represent an important virulence factor associated with the pathogenesis of different fungal infections (Sardi Jde et al., 2014). Once formed, biofilms provide a safe haven in which fungal cells can resist treatment due to their increase resistance to antifungal therapy; and cells can also disperse from these biofilms to cause disseminated infections in target organs (Ramage et al., 2009; Uppuluri et al., 2010a). As such, biofilm formation results in increased mortality rates and associated economic costs.

Candidiasis is now the third most common nosocomial infection and a large proportion of these infections in different clinical settings involves biofilm formation (Kojic and Darouiche, 2004; Ramage et al., 2006). *Candida albicans* remains the most frequent causative agent, but infections caused by other non-*albicans* *Candida* spp., including among others *Candida glabrata*, *Candida parapsilosis*, *Candida dubliniensis* and *Candida tropicalis*, are also associated with the formation of biofilms (Sardi et al., 2013). Different *Candida* strains vary in their biofilm-forming ability, and this correlates with their pathogenicity potential in patients (Tumbarello et al., 2012). Of note, *Candida* spp. represent the third leading cause of central catheter-related infections associated with the formation of biofilms, with the second highest colonization-to-infection rate and the overall highest crude mortality (Crump and Collignon, 2000). Other clinical manifestations such as vaginal and oral candidiasis, as well as denture stomatitis, are also associated with a biofilm etiology (Harriott et al., 2010; Ramage et al., 2006, 2004).

Other yeasts and filamentous fungi are also capable of forming biofilms on biological and/or artificial surfaces. These include the opportunistic yeasts *Cryptococcus neoformans* (the main causative agent of fungal meningoencephalitis in HIV/AIDS patients), as well as different *Trichosporon*, *Malassezia*, *Blastoschizomyces* and *Saccharomyces* species (Ramage et al., 2009; Sardi Jde et al., 2014). Even the growth of *Pneumocystis* spp. within the lung alveoli has been postulated to constitute a biofilm (Cushion et al., 2009). Dimorphic fungi, the etiological agents of endemic mycoses, such as *Coccidioides immitis*, *Histoplasma capsulatum*, *Penicillium marneffei* and *Paracoccidioides brasiliensis* can also form biofilms (Sardi Jde et al., 2014). Among filamentous fungi, perhaps the most important species capable of biofilm formation is *Aspergillus fumigatus*, the main causative organism responsible for invasive aspergillosis in cancer and transplant patients (Mowat et al., 2009). The biofilm-forming ability of other filamentous fungi, such as the Mucorales and *Fusarium* spp., has also been described (Sardi Jde et al., 2014). Unlike *Candida*, several of these opportunistic pathogenic fungi are also ubiquitous in nature, and it is conceivable that biofilm formation can play a role in their persistence and survival in the environment (Martinez and Casadevall, 2007; Pini et al., 2005; Ravi et al., 2009). In this case, it is possible that the extracellular matrix increases resistance to UV light, de-hydration, predation and other environmental threats.

This article is a reprint of T. Vila, D. Montelongo-Jauregui, J.A. Romo, G. Wall, C.G. Pierce, J.L. López-Ribot, Fungal Biofilms, *Reference Module in Life Sciences*, Elsevier, 2017.

Development of Fungal Biofilms

Architectural Features of Fungal Biofilms

Fungal biofilms are defined as highly structured and organized consortia of cells attached to a substrate, either biological or artificial, and encased within a self-produced matrix of exopolymeric material Fig. 1. Although their structural properties can vary depending on the fungal species, the type of substrate and the growing conditions, overall fungal biofilms typically display a complex three-dimensional architecture with extensive spatial heterogeneity, including microcolonies and ramifying water channels (Blankenship and Mitchell, 2006; Chandra et al., 2001; Nett and Andes, 2006; Ramage et al., 2001b, 2005). This constitutes an almost optimal spatial arrangement for the uptake of nutrients, excretion of metabolic products, and for cell-to-cell communication, and may include some degree of specialization of cells depending on the location that they occupy within the biofilm. Also, the close proximity of cells within biofilms facilitates mating (Soll and Daniels, 2016).

The Different Phases of Fungal Biofilm Development

There are four major stages of fungal biofilm development. These are: (1) initial attachment and colonization, (2) proliferation, (3) maturation and (4) dispersion (Chandra et al., 2001; Ramage et al., 2009; Uppuluri et al., 2010a; Fig. 2). During the dispersion phase daughter cells, mostly in the yeast form and with increased infectivity potential, are released from the biofilm and attach at distal sites so that the “biofilm life-cycle” can start all over again (Uppuluri and Lopez-Ribot, 2016). The whole developmental process is quick and fully mature biofilms can be observed 24–48 h after the first *Candida* cell adheres to the surface or 48–72 h after the swollen *Aspergillus* spores touches the epithelial cells in the alveolar lung. In the case of *C. albicans* and also filamentous fungi, the process of biofilm formation is intimately linked to filamentation, as hyphae represent key elements for providing structural integrity and are responsible for the distinctive multi-layered architecture associated with fully developed biofilms. (Lopez-Ribot, 2005; Nobile et al., 2006a; Nobile and Mitchell, 2006; Ramage et al., 2002d; Uppuluri et al., 2010b). Quorum-sensing mechanisms (ie, cell-to-cell communication via small hormone-like molecules released by biofilm cells) as well as adhesive interactions, both cell-to-cell and cell-to-substrate, are also important during biofilm development (Nobile et al., 2006a,b, 2008; Nobile and Mitchell, 2005, 2006; Ramage et al., 2002b).

The Fungal Biofilm Matrix

As mentioned before, one of the main characteristics of fungal biofilms is the presence of a hydrated exopolymeric material that envelops the cells within the biofilms, commonly referred to as the “biofilm matrix,” which is produced by cells during biofilm maturation (Mitchell et al., 2016). From a structural point of view, the cohesive and adhesive forces of the matrix contribute to the

Fig. 1 (A) A scanning electron microphotograph showing an *Aspergillus fumigatus* biofilm (Courtesy of Dr. Gordon Ramage). (B) Three-dimensional reconstruction of a *Candida albicans* biofilm using confocal scanner laser microscopy and associated software. Bars are 20 μ m.

Fig. 2 A cartoon depicting the different phases of fungal biofilm development.

architectural and mechanical stability of the biofilm by mediating stable cell–cell and cell–surface interactions, essentially acting as a glue that holds the cells together and attached to the surface (Mitchell et al., 2016). The composition of the biofilm matrix changes according to physical, biological and environmental conditions and varies among different fungal species, but it has been demonstrated that carbohydrates and proteins constitute the most common and abundant matrix components (Mitchell et al., 2016). However, other macromolecules such as lipids and nucleic acids seem to be almost universally present in fungal biofilm matrices (Martins et al., 2010, 2012; Mitchell et al., 2016; Rajendran et al., 2013; Zarnowski et al., 2014). Moreover, the different components in the *C. albicans* biofilm matrix interact physically with each other resulting in the overall matrix displaying characteristics of an amalgam and emergent properties (Zarnowski et al., 2014). In general, biofilms formed under physiological conditions of flow display increased matrix production compared to those formed statically (Uppuluri et al., 2009a). From a physiological perspective the biofilm matrix acts as a shielding barrier, protecting against host defenses as well as preventing drugs from penetrating the biofilms, and as such contributes to biofilm resistance (see below) and to the recalcitrance of biofilms-associated infections (Mitchell et al., 2016). In polymicrobial biofilms, most commonly formed by fungal and bacteria that grows together in a mutualistic association, the fungal biofilm matrix contributes to protection of the bacterial cells against antibiotics and may even provide a hypoxic microenvironment that supports the growth of anaerobic bacteria (Fox et al., 2014; Harriott and Noverr, 2009), while matrix components secreted by the bacteria may also contribute impact resistance to antifungal agents (Montelongo-Jauregui et al., 2016).

Molecular Mechanisms Governing Fungal Biofilm Formation

Without any doubt, *C. albicans* has been the favorite fungal system used in studies by a growing number of groups trying to elucidate the molecular mechanisms underlying fungal biofilm development. Early studies established that morphogenesis plays a pivotal role during biofilm formation, with hyphae representing essential elements for providing structural integrity to fully developed biofilms (Baillie and Douglas, 1999), and already demonstrated a key role for *EFG1* as a key transcriptional regulator of biofilm development (Ramage et al., 2002d). Up-regulation of many hyphal-induced genes in biofilms detected in gene expression profiling studies corroborated these findings, and also pointed to a different metabolic signature of biofilm cells as compared to their planktonic counterparts (Garcia-Sanchez et al., 2004). *BCR1* codes for a key transcriptional regulator that activates cell-surface protein and adhesion genes required for biofilm formation, most notably cell wall mannoproteins encoded by the *ALS* gene family, and in particular *Als1p* and *Als3p*. These proteins mediate attachment and facilitate coaggregation with other fungal elements via complementary adhesins such as *Hwp1* (Nobile et al., 2006a, 2008), and they also mediate binding to bacterial cells in polymicrobial biofilms (Silverman et al., 2010; Fig. 3). The zinc-responsive transcription factor *Zap1* is the major regulator of the biofilm extracellular matrix production (Nobile et al., 2009). In addition, several key biofilm genes are involved in the quorum-sensing response to farnesol, a natural occurring inhibitor of the *Candida* yeast-to-hypha transition and important regulator of the biofilm growth. More recently, by screening a collection of *C. albicans* mutant strains, Nobile et al., demonstrated that a network of six “master” transcription regulators (*Bcr1*, *Efg1*, *Ndt80*, *Rob1*, *Tec1* and *Brg1*), now expanded to also include *Flo8*, *Gal4* and *Rfx2*, orchestrates biofilm formation in this opportunistic pathogen (Fox et al., 2015; Nobile et al., 2012). The overall biofilm network is large, with approximately one thousand genes and twice that many connections, pointing to a high level of complexity associated with biofilm development. Interestingly, from an evolutionary point of view, this biofilm network seems to have evolved relatively recently in *C. albicans*, with a preponderance of “young” as compared to “old” genes, and this may have important repercussions in its adaptation to the mammalian host and pathogenic potential (Nobile et al., 2012). Not all biofilms are created equal, and in particular the configuration of the mating type locus (*MTL*) has a profound influence on biofilm thickness and function, which can translate in species- and strain-specific functional characteristics and further complicate biofilm elimination/treatment (Soll and Daniels, 2016). As discussed previously, dispersion of yeast cells from the biofilm is an important developmental phase of

Fig. 3 Scanning electron microphotograph showing a polymicrobial biofilm of *Candida albicans* and the bacterium *Streptococcus gordonii*. The fungal and bacterial elements have been pseudocolored. Bar is 20 μ m.

C. albicans biofilms as it allows the dissemination of infectious particles, favoring invasive life-threatening infections (Uppuluri et al., 2010a; Uppuluri and Lopez-Ribot, 2016). Ume6, Pes1, Nrg1 and Hsp90 have been identified as key regulators of the release of cells from a biofilm (Robbins et al., 2011; Uppuluri et al., 2010a,b) and understanding the main pathways that control the release of cells from the biofilm may help elucidate ways to curtail dispersion and control the related infection (Uppuluri and Lopez-Ribot, 2016).

Antifungal Drug Resistance of Fungal Biofilms

As mentioned before, fungal biofilm formation carries important negative consequences since cells within the biofilms tend to display high levels of resistance to a majority of clinically used antifungal agents (Pierce et al., 2013; Uppuluri et al., 2009b). As such the formation of biofilms by many fungal species further complicates antifungal therapy in an expanding population of at-risk patients and represents a major contributor to the high mortality rates associated with these infections.

Fungi are eukaryotic and there is paucity of targets which can be exploited for antifungal drug development. As a result, the antifungal arsenal is exceedingly short, and in particular for the treatment of invasive fungal infections is restricted to three classes of antifungal agents, polyenes (ie, amphotericin B), azoles (ie, fluconazole) and echinocandins (ie, caspofungin) (Ostrosky-Zeichner, et al., 2010; Pierce et al., 2013). Polyenes bind to ergosterol and compromise the integrity of the fungal membrane, azoles inhibit synthesis of ergosterol which is the main sterol in the fungal membrane, whereas echinocandins inhibit synthesis of glucan, a key structural component of the fungal cell wall. Unfortunately, it is well documented that fungal biofilms are intrinsically resistant to azoles; for example, preformed biofilms of *Candida* spp. are up to 1000 times more resistant to fluconazole compared to planktonic populations (Ramage et al., 2001a); however, voriconazole (and other azoles derivatives) can inhibit biofilm formation in different *Candida* species (Valentin et al., 2012). Fungal biofilms also showed decreased susceptibility to polyenes; although amphotericin B exhibits biofilm activity, it does so at high concentrations which are usually considered toxic and unsafe (Ramage et al., 2002c). Subsequent reports indicated excellent activity of liposomal formulations of Amphotericin B against *Candida* biofilms (Kuhn et al., 2002). Of note, all echinocandin derivatives seem to display excellent anti-biofilm activity even at relatively low therapeutic concentrations. Initial reports demonstrated the potent activity of caspofungin (the first echinocandin to reach the market) against *C. albicans* biofilms in vitro (Bachmann et al., 2002; Kuhn et al., 2002), and subsequent experiments expanded these observations to micafungin and anidulafungin, also in the case of different *Candida* spp. (Kucharikova et al., 2011). These findings were further corroborated in in vivo models and in clinical practice (Kucharikova et al., 2013, 2010; Tumbarello et al., 2012). Therefore, one could argue that the potent anti-biofilm activity of echinocandins has been one of the main factors responsible for this class of antifungals becoming first line therapy against candidiasis, particularly when biofilm formation is suspected (ie, catheter-related candidemia) (Pappas et al., 2009; Tumbarello et al., 2012). However it is important to note that the anti-biofilm activity of echinocandins is not universal. A more recent report indicated drug and species specific differences in their anti-biofilm activity, with *Candida lusitanae* and *Candida guilliermondii* biofilms exhibiting reduced susceptibility to this new class of antifungals (Simitsopoulou et al., 2013). Furthermore *A. fumigatus* biofilms are relatively resistant to echinocandins (Ramage et al., 2009, 2012), and this class of drugs is not active against other opportunistic fungi frequently associated with biofilms, like *Cryptococcus*, *Mucorales* and *Fusarium*.

Mechanisms of Antifungal Drug Resistance

The investigation of the mechanisms responsible for the antifungal drug resistance of fungal biofilms at the molecular level has been an area of intensive study. Overall, there is a general agreement that fungal biofilm resistance is a complex multifactorial phenomenon involving distinct molecular mechanisms of resistance as compared to planktonic cells Fig. 4. Different groups of investigators have demonstrated the contribution of different mechanisms to fungal biofilm resistance including: (1) the increased cellular density of fungal cells within the biofilm, basically a simple concept of “safety in numbers,” as elegantly demonstrated by the Chaffin’s group (Perumal et al., 2007); (2) the existence of subpopulations of “persister” cells, dormant variants that are highly tolerant to the action of antifungals (LaFleur et al., 2006, 2010); (3) distinct physiological and metabolic signatures of biofilm cells (Baillie and Douglas, 1998a,b); (4) changes in sterol composition of the cell membrane of biofilm cells, most notably decreased levels of ergosterol; (5) an important protective role for the biofilm matrix, predominantly due to binding of azoles and polyenes to matrix glucans (Al-Fattani, and Douglas, 2006; Nett et al., 2007; Nobile et al., 2009) and extracellular DNA (Martins et al., 2012); (6) the differential expression of genes linked to resistance, particularly those encoding drug transporter resulting in increased efflux of antifungal molecules (Mukherjee et al., 2003; Ramage et al., 2002a); (7) a complex and highly orchestrated network of cellular responses mostly mediated by the hsp90 molecular chaperone (Robbins et al., 2011).

Conclusions and Future Outlook

It is now widely recognized that a number of fungal infections are associated with biofilm formation. Formation of fungal biofilms complicates therapy and contributes to mortality, also with soaring economic consequences. Although much information has been accumulated concerning *Candida* and *Aspergillus* biofilms, little is known regarding less frequent but highly threatening agents, such

Fig. 4 Multiple factors contributing to fungal biofilm resistance.

as the Mucorales and *Fusarium* spp. It is our hope that the increasing understanding of mechanisms involved in fungal biofilm development and resistance at both the cellular and molecular levels, together with the increased recognition and awareness of the importance of these infections by the medical communities, will eventually lead to novel strategies for better clinical management and will offer new hope for a growing number of patients suffering from these devastating infections.

Glossary

Cell wall Structural network that surrounds the lipidic cell membrane in bacteria, fungi and plants, and that confers structural maintenance (rigidity) and osmotic stability to the cells.

Chitin Polysaccharide obtained after the polymerization of N-acetyl glucosamine.

Dendritic cells Phagocytic cells whose main function is the presentation of antigens from internalized pathogens to other immune cells (mainly CD4, CD8 and B cells).

Endocytosis Process that results in the internalization of exogenous components by cells. When the cells internalize solid particles, it is referred as phagocytosis.

Exosomes Small intraluminal vesicles (30–150 nm) released when multivesicular bodies (MVBs) fuse with the plasma membrane.

Extracellular vesicles Any bilayered compartment released by living cells.

Galleria mellonella A lepidopteran species widely used as an alternative model of host in infectious disease research.

Glucan Polysaccharide composed of glucose monomers bound through glycosidic bonds.

Laccase Enzyme also known as diphenol oxidase, which is involved in some fungi in melanin synthesis from specific substrates, such as L-DOPA.

Lipid raft Membrane micro-compartment enriched in sterols, sphingolipids, glycolipids and GPI-anchored proteins that regulate functions such as endocytosis and cellular signaling.

Macrophages Specific type of white blood cells (leukocyte) specialized in the uptake and degradation of exogenous particles. There are two types of macrophages: M1 (also known as classical or proinflammatory macrophages), which have a strong antimicrobial activity, and M2 (also known as alternative or anti-inflammatory macrophages), which have an immunoregulatory function.

Mannan Polysaccharide formed by polymerization of mannose monomers. Can be divided in **N-linked mannan** (polymer attached to an asparagine through a nitrogen atom) or **O-linked mannans** (attached to a serine or threonine through an oxygen atom).

Microvesicles Extracellular vesicles that are formed by direct plasma membrane budding.

Th1 and Th2 immune response Defense mechanism elicited by hosts that protect from external challenges, mainly microbes and toxic compounds. Th1 and Th2 are different types of immune response, being Th1 those known as inflammatory, and Th2 as anti-inflammatory.

Abbreviations

AE	Atopic eczema
APT1	Aminophospholipid translocase 1
CD	Cluster of differentiation
Chitin	β -1,4-poly-N-acetyl-D-glucosamine
CHS	Chitin synthase
Cln1	G1/S cyclin 1
DC-SIGN	Dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin
DLS	Dynamic light scattering
EVs	Extracellular vesicles
GAPDH	Glyceraldehyde 3-phosphate dehydrogenase
GlcCer	Glucosylceramide
GRASP	Golgi reassembly and stacking protein
GSL	Glycosphingolipids
GXM	Glucuronoxylomannan
HBMEC	Human brain microvascular endothelial cells

HSP60	Heat shock protein 60
IL-10	Interleukin-10
IL-12	Interleukin-12
mAb	Monoclonal antibody
MHCII	Major histocompatibility complex class II
MP65	Mannoprotein 65
PBMC	Peripheral blood mononuclear cells
PCA3	Prostate cancer antigen 3
PSA	Prostate-specific antigen
RNA	Ribonucleic acid
TGF β	Transforming growth factor β
TNF α	Tumor necrosis factor α
WT	Wild type

Biogenesis of Fungal EVs

EVs are produced virtually by all living organisms, including bacteria, fungi, plantae, protozoa and mammals (Marcilla et al., 2014; Brown et al., 2015; Rodrigues et al., 2015; Yanez-Mo et al., 2015). The term “EVs” is used to designate any bilayered compartment released by alive cells. In fungal organisms it includes exosome-like particles, microvesicles (also named ectosomal or shedding vesicles) and compartments generated by cytoplasmic subtractions (Gyorgy et al., 2011; Rodrigues et al., 2013) (Fig. 1). Exosomes are small intraluminal vesicles (30–150 nm) released when multivesicular bodies (MVBs) fuse with the plasma membrane (Fig. 1 (A)) (Yanez-Mo et al., 2015; Rashed et al., 2017) (Fig. 1(A)). Microvesicles are usually larger (100–1000 nm) and assembled by direct plasma membrane budding (Fig. 1(B)). Cytoplasmic subtractions due to plasma membrane reshaping were recently described in *Saccharomyces cerevisiae* (Rodrigues et al., 2013). They are formed through an invagination process followed by a reorientation of the invaginating membrane to the plasma membrane, with subsequent membrane fusion and release of vesicles into the periplasmic space (Fig. 1(C)). Fungal EVs usually consist of one or two populations ranging between 50–250 and 300–800 nm (Albuquerque et al., 2008; Rodrigues et al., 2008; Oliveira et al., 2010; Wolf et al., 2014, 2015; Brown et al., 2015; Vargas et al., 2015). Differences in electron density between fungal EVs have been demonstrated, supporting the idea that EVs could have

Fig. 1 Fungal EVs biogenesis. EVs are formed through at least three distinct mechanisms: (A) multivesicular bodies fusion with plasma membrane releasing exosomes, (B) plasma membrane budding and (C) cytoplasmic subtraction. In all cases the EVs could reach the extracellular environment intact.

Table 1 Related functions for proteins characterized in fungal extracellular vesicles

Related functions for proteins characterized in fungal extracellular vesicles:

 Carbohydrate metabolism
 Cell wall architecture
 Amino acid and Protein metabolism
 Ribosomal proteins
 Cellular organization and biogenesis
 Cell signaling
 Response to stress
 Endocytic route

multiple biogenesis pathways resulting in distinct cargo (Rodrigues et al., 2008). Remarkably, even strains of the same species can produce EVs with distinct sizes, confirming the heterogeneity of these compartments (Vargas et al., 2015).

Major components of the cell wall include chitin, β -1,3 and β -1,6 glucans and mannoproteins (regularly found as an outer cell wall layer of *C. albicans* and *S. cerevisiae*).

Fungal EVs Cargo

The mechanisms mentioned above are compatible with distinct vesicle sizes and high diversity of structures carried by fungal EVs, including proteins lacking secretory signals, metabolic enzymes, RNA, pigment and polysaccharides (reviewed in Nimrichter et al., 2016). A number of EV components are conserved among different fungal species and strains, but some are species-specific (Vallejo et al., 2012a, b). The major lipids characterized in fungal EVs are glucosylceramide (GlcCer), sterols and phospholipids (Rodrigues et al., 2007; Albuquerque et al., 2008; Vallejo et al., 2012a, b; Vargas et al., 2015). The variety of proteins carried by fungal EVs is enormous (Table 1) and includes proteins involved with multiple metabolic pathways (Rodrigues et al., 2008; Vallejo et al., 2012a, b; Rodrigues et al., 2014; Wolf et al., 2014; Gil-Bona et al., 2015; Vargas et al., 2015; Wolf et al., 2015; Matos Baltazar et al., 2016; Nimrichter et al., 2016).

Unexpectedly, major hits found in EVs from distinct fungal species included enzymes involved with glycolysis, fermentation, gluconeogenesis, pentose phosphate, tricarboxylic acid, and glyoxylate cycles (reviewed in Nimrichter et al., 2016). At least some of these enzymes are involved in fungal adhesion to host cells, such as enolase, GAPDH and phosphoglycerate mutase (Nimrichter et al., 2016). However, their participation during EV recognition by host cells has never been investigated. It is plausible that release of fungal EVs loaded with metabolic enzymes can be a mechanism for a rapid change in cell metabolism. Polymers such as polysaccharides and melanin are also carried by EVs (Rodrigues et al., 2007; Eisenman et al., 2009). Recently, the presence of RNA was characterized in fungal EVs from several species (da Silva et al., 2015). RNA-containing vesicles could be responsible for biological processes triggered in host cells during fungal infection or participate during communication among fungi or even with other organisms.

Traversing the Cell Wall

The plasma membrane is the interface between mammalian cells and the extracellular environment. In contrast, fungal organisms are encased in a thick cell wall, which demands EVs to cross this barrier to be released into the extracellular environment (Rodrigues et al., 2013, 2015). In encapsulated fungal cells, such as those belonging to the *Cryptococcus* complex, EVs must also traverse the capsule (Rodrigues et al., 2007). The mechanisms by which fungal EVs traverse fungal outer layers and reach the extracellular environment is still unclear.

Cell wall composition can change considerably according to the fungal species and/or morphological stage (reviewed by Erwig and Gow, 2016). However, some common compounds are widely known. These compounds form a network that is basically composed by a matrix of polysaccharides where different classes of proteins and lipids are embedded (Nimrichter et al., 2005). In most species the presence of melanin has been reported (Gomez and Nosanchuk, 2003). The major structural polysaccharides include chitin and glucans and N or O-linked mannans (review in Latge, 2010). The most common prototypes for study of fungal cell walls are *S. cerevisiae* and *C. albicans*, where a layer of mannoproteins is depicted at the edge of the cell wall (Erwig and Gow, 2016). However, other species can have polysaccharides or hydrophobins, such as *Histoplasma capsulatum* and *Aspergillus* conidia, respectively, as outer layers (Erwig and Gow, 2016). In order to support turgor pressure and also permit budding and morphological changes the cell wall must be robust, elastic and very dynamic.

After their release at the periplasmic space, fungal EVs presumably interact with cell wall components. The exact number of EVs produced by each fungal cell is not known. Although mechanical pressure could facilitate EV passage through the wall (Brown et al., 2015), other mechanisms were proposed. For instance, Anderson and colleagues demonstrated the presence of channels at the cell wall of *C. albicans* (Anderson et al., 1990). Cell wall protuberances were associated with the edge of these channels where small

vesicles were depicted. In addition, flask-shaped vesicles were observed underneath the base of these protuberances (Anderson et al., 1990). In *C. neoformans*, Wolf and colleagues (Wolf et al., 2014) demonstrated that EVs interact directly with the cell wall. Notably, they also observed multiple or single leaving events between the plasma membrane and the cell wall. Thus the release of EVs in *C. neoformans* does not appear to be linked to channels.

EV-mediated cell wall hydrolysis was also proposed as a mechanism facilitating their passage through the cell wall. In fact, EVs isolated from cultures of *C. neoformans*, *Paracoccidioides brasiliensis*, *H. capsulatum* and *C. albicans* carry a number of glycosidases including, chitinases, glucosidases and mannosidases (Nimrichter et al., 2016). Lipases and proteases are also transported by EVs. Although the activity of cell wall-related enzymes was never reported in *C. neoformans* EVs, active laccase and urease were detected biochemically, supporting the notion that other enzymes can be also functional (Rodrigues et al., 2008). However, direct EV-mediated hydrolysis has never been demonstrated.

In fungi, production of chitin and glucans occurs at the plasma membrane level (Latge, 2007). Once the newly synthesized polysaccharides are extruded to the cell wall they can be modified by cell wall enzymes. Polysaccharides are then cross-linked to each other or to GPI-remnant proteins (De Groot et al., 2005; Latge, 2007). Proteomic analysis suggested that fungal EVs also participate in cell wall synthesis (Albuquerque et al., 2008; Vallejo et al., 2012a, b; Rodrigues et al., 2014; Gil-Bona et al., 2015; Vargas et al., 2015). Chitin synthases were reported in EVs released by *H. capsulatum*, *C. neoformans* and *P. brasiliensis* (Nimrichter et al., 2016). Some chitin synthases are regulated by protease activity (Sburlati and Cabib, 1986). For instance, two chitin synthases (CHS1 and CHS2) from *S. cerevisiae* are more active after trypsin or chymotrypsin treatment (Duran and Cabib, 1978; Sburlati and Cabib, 1986) while the third one (CHS3) is inactivated (Orlean, 1987; Valdivieso et al., 1991). Thus, fungal EVs could potentially contribute to chitin synthesis directly, by their chitin synthases, or indirectly, through their proteolytic activity. Furthermore, EVs from *C. neoformans* carry chitin-deacetylase, an enzyme that converts chitin into chitosan. In this pathogen, chitosan is required for cell wall integrity (Baker et al., 2007). The absence of chitosan affects capsular size and promotes a "leaky" melanin phenotype (Baker et al., 2007).

Host Cell Modulation and Impact on Disease Development

Since fungal EVs carry a combination of virulence factors, it has been speculated that they could impact host cell responses (Oliveira et al., 2010; Huang et al., 2012; Vargas et al., 2015; Wolf et al., 2015; da Silva et al., 2016). EVs from *C. neoformans* and *C. albicans* co-localized with the lipid raft marker GM1 at the surface of macrophages and dendritic cells (Oliveira et al., 2010; Vargas et al., 2015). Fusion between fungal EVs and the host plasma membrane was not detected. EVs were internalized after few minutes of interaction, with a complete internalization after 1 h (Vargas et al., 2015). Exposure for longer periods demonstrated that EVs from *C. neoformans* and *C. albicans* are not toxic to primary mammalian cells (Oliveira et al., 2010; Vargas et al., 2015). Together these findings indicate that cell surface receptors are required for EV association with and internalization by phagocytes. Accordingly, Peres da Silva and colleagues reported that EVs from *P. brasiliensis* display mannose and N-acetylglucosamine residues that could be recognized by DC-SIGN (Peres da Silva et al., 2015). Internalization of fungal EVs by phagocytes culminated with production of nitric oxide and cytokines such as IL-12, IL-10, TNF α and TGF β , confirming their immunomodulatory activity (Oliveira et al., 2010; Vargas et al., 2015). In addition, the fungicidal activity of macrophages was increased after exposure to EVs from *C. neoformans* or *P. brasiliensis* (Oliveira et al., 2010; da Silva et al., 2016). Furthermore, *P. brasiliensis* EVs promoted M1-polarization in macrophages and reversed the M2-polarization stimulated by IL-4/IL-10 (da Silva et al., 2016). The M1 phenotype is important for host defense during phagocytosis and killing by macrophages (Murray and Wynn, 2011). During chronic paracoccidioidomycosis the majority of macrophages are M2, favoring a Th2 response and the susceptibility to the infection (de Carli et al., 2016). Thus, EVs could contribute to paracoccidioidomycosis control.

The ability of fungal EVs to stimulate human cells was also observed. Gehrman and colleagues showed that *Malassezia sympodialis*, a commensal yeast linked to atopic eczema (AE), releases EVs loaded with allergens (Gehrman et al., 2011). *M. sympodialis* EVs were able to stimulate the production of TNF α and IL-4 by CD14- and CD34-depleted PBMC from healthy and AE patients. Remarkably, the response was significantly higher in *M. sympodialis* sensitized patients (Gehrman et al., 2011). Collectively these results suggested that fungal EVs could activate cells of the innate immune system. Indeed, the capacity to stimulate the immune system was confirmed using *Galleria mellonella* larvae. *G. mellonella* immune mechanisms share a high degree of structural and functional homology to those used by the innate immune system of vertebrates (Browne et al., 2013). Treatment of *G. mellonella* larvae with EVs from *C. albicans* protected the insect against a subsequent challenge with the pathogen (Vargas et al., 2015). The number of viable yeasts recovered from EV-treated larvae was significantly reduced when compared to PBS-treated larvae. These results were accompanied by a higher percentage of larvae survival in the presence of fungal EVs.

Besides impacting the innate immune response, host cell activation mediated by fungal EVs could also change the outcome of the adaptive immune response as treatment of dendritic cells with EVs from *C. albicans* enhanced the surface expression of CD86 and MHC-II (Vargas et al., 2015). At least in part, this property could be linked to the high levels of MP65, a major protein in *C. albicans* EVs (Gil-Bona et al., 2015; Vargas et al., 2015). MP65 is a major mannoprotein at *C. albicans* cell surface (Gil-Bona et al., 2015). *In vitro*, MP65 stimulates dendritic cells inducing cytokine production, such as TNF- α and IL-6, and increases the expression of costimulatory molecules. These results indicate that fungal EVs can be potential antigen carriers to be explored in vaccine formulations.

The ability of fungal EVs to interact with host cells was also investigated in human brain microvascular endothelial cells (HBMEC) (Huang et al., 2012). Remarkably, treatment of HBMEC with EVs from *C. neoformans* induced fusion of the host cells and stimulated redistribution of membrane proteins in lipid rafts. The proteins CD44, a known receptor for *C. neoformans* in HBMEC (Jong et al., 2008), and caveolin-1 were significantly enhanced in lipid rafts fractions after exposure to EVs (Huang et al., 2012). In contrast, a significant reduction in raft-associated β -actin was observed. Thus, EVs from *C. neoformans* are able to activate HBMEC and promote changes that facilitate fungal adhesion and their ability to cross the brain blood barrier *in vitro*. Experiments *in vivo* confirmed that *C. neoformans* EVs could potentially impact disease development. Intravenous injection of EVs in a murine model of cryptococcosis significantly increased the fungal burden in the brain (Huang et al., 2012).

Genetically Modified Strains as Tools to Investigate Fungal EVs

As mentioned previously, fungal EVs were isolated for the first time from *C. neoformans* cultures (Rodrigues et al., 2007). To this date, most of the information based on genetic alterations and EV release in fungal pathogens comes from this model. The attempts to impair fungal EV release in genetically modified strains generally failed, although important differences in EV properties were observed. The first gene investigated was *SEC6*, which encodes a protein that participates in the fusion of exocytic vesicles with the plasma membrane in yeasts (TerBush et al., 1996). Panepinto and colleagues investigated the role of Sec6 during EV-mediated release of virulence factors by *C. neoformans* (Panepinto et al., 2009), including the enzymes phospholipase, urease and laccase, and the major capsular polysaccharide glucuronoxylomannan (GXM) (Rodrigues et al., 2008). Notably, laccase and urease activities were significantly reduced in *iSEC6* cells. In addition, the amount of secreted GXM was also decreased (Panepinto et al., 2009). Sec6 suppression in *C. neoformans* led to vesicle accumulation in the cytoplasm and abrogated EV release. In *iSEC6* cells laccase was restricted to the cytoplasm within vesicular compartments. Although phospholipase activity and capsular size were not affected in the *SEC6* knockout, the *iSEC6* strain was less virulent than WT cells. Fungal EVs appeared to be responsible for the correct transport of virulence factors to the cell surface, contributing to the disease development.

The influence of proteins that regulate membrane asymmetry in EV properties was investigated in *C. neoformans* (Rizzo et al., 2014). The gene *APT1* encodes a putative aminophospholipid translocase, a class of proteins named as flippases. Their role in membrane asymmetry helps to control trafficking events that precede secretion. Flippases were linked to EV production in *C. elegans* (Tuck, 2011; Wehman et al., 2011). In *C. neoformans* APT1 is required for protein secretion and pathogenicity (Hu and Kronstad, 2010). Deletion of *APT1* affected Golgi morphology and GXM secretion, but not capsule size and GXM composition (Rizzo et al., 2014). The amount of GXM found in EVs from yeasts lacking APT1, however, was considerably reduced when compared to vesicles obtained from WT cells (Rizzo et al., 2014).

The connections between proteins involved with unconventional secretion mechanisms and export of fungal molecules were explored in a few studies. In eukaryotes, Golgi reassembly and stacking protein (Grasp) participates in unconventional mechanisms of secretion (Kinseth et al., 2007). Deletion of *GRASP* in *C. neoformans* affected Golgi morphology (Kmetzsch et al., 2011) and reduced the dimensions of extracellular polysaccharides, as determined by dynamic light scattering (DLS). These results were reverted by addition of Ca^{2+} to the system, allowing GXM aggregation through calcium bridges (Nimrichter et al., 2007; Kmetzsch et al., 2011). In agreement with the reduction in extracellularly released GXM the mutants also displayed a hypocapsular phenotype. Recent data from our laboratory suggested that *GRASP* deletion affects EV populations of lower dimensions, suggesting that Grasp participate in vesicle biogenesis (Luna S. Joffe, unpublished data). EVs are affected by other cryptococcal genes. A considerable increase in EV release was observed in a *C. neoformans* strain lacking *Cln1*, a protein involved with cell cycle progression (Garcia-Rodas et al., 2014). In addition, deletion of *CAP10*, a putative xylosyltransferase, resulted in EVs with significantly reduced dimensions (Tefsén et al., 2014). Notably, increased laccase and acid phosphatase activities were observed at the fungal cell surface.

The relationship between secretory genes and EV formation was more deeply explored in *S. cerevisiae*. Vesicle dimensions and protein composition were analyzed in mutants lacking either conventional or unconventional secretory regulators. All mutants produced EVs, but amounts, composition and dimensions varied depending on the gene deleted. No direct correlation was established between secretory mechanisms (conventional or unconventional) and EV formation, since all genes were apparently required for normal vesicle release. These results are summarized in Table 2.

Table 2 Effects of gene deletion on the properties of *S. cerevisiae* EVs

Gene product	Associated secretory pathway	Average EV dimensions	Protein composition	EV amount
Sec4	Conventional	Increased	Slightly affected	Reduced
Bos1	Conventional	Not determined	Slightly affected	Not determined
Sec1	Conventional	Not determined	Slightly affected	Not affected
Snf7	Unconventional	Not affected	Heavily affected	Not affected
Vps23	Unconventional	Not determined	Slightly affected	Not determined
Grasp	Unconventional	Not determined	Not determined	Reduced

EVs as Targets of New Antifungal Drugs and Protective Antibodies

The potential participation of fungal EVs in physiological events and disease development suggests that they can become interesting targets for antifungal drugs and antibodies. As mentioned above GlcCer is a glycosphingolipid (GSL) component of fungal EVs (Rodrigues et al., 2007; Vallejo et al., 2012a,b; Vargas et al., 2015). Besides its structural function, GlcCer is also a virulence regulator in *C. neoformans* and *C. albicans* (Rittershaus et al., 2006; Noble et al., 2010). Recently, Mor and colleagues identified a new class of antifungal drugs that indirectly impact the synthesis of GlcCer. One of the effects was the accumulation of intracellular vesicles in yeasts of *C. neoformans* (Mor et al., 2015). Other drugs that impact lipid biosynthesis or proteins involved with EVs biogenesis could impair release of EVs and change the fungal physiology. For instance, Knechtle and colleagues identified a plant derived diene-furan fatty acid named as EV-086 as a potent antifungal drug (Knechtle et al., 2014). This compound targets delta-9-fatty acid desaturation increasing the ratio of saturated/unsaturated fatty acids. Accumulation of saturated fatty acid would impact directly the membrane composition and fluidity (Ballweg and Ernst, 2017). Consequently, the function of several proteins could be modified as well as the biogenesis, cargo and release of EVs. These possibilities require experimental confirmation.

Administration of monoclonal antibodies (mAbs) that recognize structures carried by fungal EVs could be another strategy to impact EV activity during disease development. Three probable mechanisms are expected for mAb to interfere with fungal EVs *in vivo*, including (i) removal of released EVs, reducing their potential deleterious effect in host cells, (ii) preventing initial passage through the cell wall or (iii) impacting gene regulation in fungal metabolism. All these three mechanisms were previously described in models of fungal infections involving protective mAbs (Eisenman et al., 2005; McClelland and Casadevall, 2012). Indeed, it could explain why mAb to GlcCer promotes a protective effect in a cryptococcosis murine model (Rodrigues et al., 2007). Recently, Baltazar and colleagues investigated whether mAbs to HSP60 impact release and cargo of EVs in *H. capsulatum* yeast cells (Matos Baltazar et al., 2016). Noteworthy, HSP60 is a major EV compound in the *H. capsulatum* model (Albuquerque et al., 2008). Incubation of yeasts with mAb-HSP60 significantly changed the size of EVs, as well as their protein content and enzymatic activities. Remarkably, changes in protein composition varied depending on the epitope recognized by mAbs to HSP60 (Matos Baltazar et al., 2016). This observation confirms that antibody binding can modify the EV release to the extracellular environment.

Challenges in the Field of Fungal EVs

Although the number of publications and findings regarding fungal EVs increased significantly over the last decade (Joffe et al., 2016), there are unsolved questions that require further investigation. One major concern is whether EVs are released by fungal cells *in vivo*, as well as their amounts, and whether they contribute or not to infection development. Isolation of fungal EVs from infected tissues will likely represent a breakpoint in the field. On the basis of the current literature, it is plausible that EVs isolated *in vivo* could show considerable changes in composition when compared with EVs from culture supernatants. Furthermore, one must consider that EVs released during infection could express a mixture of fungal and host molecules, which makes these analyses even more complex. Although a number of methods can be used for EV preparation, successful protocols require a high recovery of EVs using small volumes of samples. The standard methods are differential and density gradient centrifugation, but the viscosity of some biological fluids and the similar densities between some EVs limit the use of centrifugation methods. EV markers are now known in mammalian samples (reviewed in Xu et al., 2016). For instance, survivin, PSA and PCA3 are exosome markers for prostate cancer in urine samples (Nilsson et al., 2009). Monoclonal antibodies have been used as tools to isolate EVs, including distinct subtypes, using immunological methods and commercial kits (Taylor et al., 2011; Lasser et al., 2012; Vlassov et al., 2012; Ghosh et al., 2014; Hudson et al., 2014; Enderle et al., 2015; Lobb et al., 2015; Brett et al., 2017). The absence of a fungal EV marker is challenging to the field. GlcCer seems to be an interesting fungal EV-marker candidate, although some species including *C. glabrata* and *S. cerevisiae* are unable to produce this GSL (Tavares et al., 2008). Protein markers would also facilitate separation of EVs originated from distinct biogenesis pathways. Finally, the participation of fungal EVs during cell-to-cell communication has never been demonstrated, although indirect evidence suggested that it could occur *in vitro* during fungal differentiation (Leone et al., 2017).

Glossary

Adaptive immunity An arm of the immune system that responds to microorganisms in a specific manner. The adaptive immune response consists of antibodies or T lymphocytes generated to fungal antigens and is based on immune memory.

Dimorphism The ability of fungi to grow as two morphologies in response to temperature. Usually these fungi grow as filamentous forms at ambient temperatures and as yeasts at 37 °C.

Hyphae Filamentous cells characterized by parallel cell walls.

Immunosuppression An impaired immune system as a result of chemotherapy for cancer, conditioning prior to transplantation, treatment with anti-inflammatory drugs such as steroids, or diseases such as advanced HIV infection.

Innate immunity An arm of the immune system that responds to microorganisms in a generalized manner by phagocytic cells. This is usually the first line of defense against infection. The innate immune system confers protection against fungi in the absence of specific antibodies or T lymphocytes previously generated prior to infection.

Mold Fungi that grow exclusively in the hyphal morphology.

Opportunistic pathogen A microorganism that tends to cause disease in individuals with impaired host defenses. Many fungi cause disease in patients with cellular immunity defects or suppression.

Phylogenetics The science that utilizes genetic relatedness to classify organisms.

Transformation A system to introduce DNA into microorganisms. This tool allows for the study of the effects of gene function on virulence or infectivity.

Abbreviations

ABPA	Allergic bronchopulmonary aspergillosis
AIDS	Acquired immunodeficiency syndrome
CF	Complement fixation
CNS	Central nervous system
CSF	Cerebrospinal fluid
EIA	Enzyme immunoassay
HIV	Human immunodeficiency virus
ID	Immunodiffusion
MTL	<i>MAT</i> -type-like loci
PAMPs	Pathogen-associated molecular patterns
PEG	Polyethylene glycol
TLRs	Toll-like receptors

Defining Statement

Systemic fungal infections are infections of organs or tissues other than the skin or mucosal surfaces. These infections have increased in frequency and importance in recent years. This article reviews the fungi that cause most systemic infections in people and the key features of the diseases these fungi cause.

Introduction

Before the 1980s, serious fungal infections were relatively uncommon, occurring mostly in patients with cancer or other underlying conditions that cause severe immunodeficiency. Since then, several developments have greatly expanded the population at risk for

[☆]*Change History:* July 2014. Janet F Staab extensively updated section 'Molecular Approaches for Studying Fungal Pathogenesis' and Table 5 to reflect newer nucleic acid sequencing methods and completed genomes data. Wong updated epidemiology of coccidiomycoses, and *C. gattii*; treatment of *Candida* fungemia and diagnosis of *Pneumocystis*. Staab and Wong updated section 'Further Reading' to add recent journal publications.

This article is an update of J.F. Staab, B. Wong, Fungal Infections, Systemic, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 389–411.

developing these fungal infections. These include advances in the treatment of many forms of cancer, advances in solid organ and stem cell transplantation, the ongoing human immunodeficiency virus (HIV) epidemic, and the widespread availability and use of antibiotics that are effective against a broad range of bacteria. For these reasons, the incidence and importance of serious fungal infections have increased markedly in the past 20 years. For example, data collected from community and teaching hospitals throughout the United States showed that the frequency of fungal bloodstream infections increased by more than threefold during the 1990s, when the frequency of Gram-positive and Gram-negative bacterial bloodstream infections changed little. Similarly, deaths from fungal infections in the United States increased more than threefold between the early 1980s and the mid-1990s. Thus, it is now clear that fungi are very important human pathogens that warrant attention and study.

Classification of Pathogenic Fungi

Fungi are among the most abundant and diverse of all organisms, but only a few species are responsible for a large majority of serious fungal infections in humans. The most important of these fungal pathogens of humans are listed according to traditional phylogenetic categories in Table 1. These classifications are based on the traditional growth and morphology of vegetative and reproductive fungal forms and also on genetic relatedness as determined by genome sequencing, especially of highly conserved elements like ribosomal DNA sequences. Most of the fungi that cause serious infections in humans are members of the phylum Ascomycota, although a few are members of Basidiomycota or Zygomycota.

Traditional phylogenetic classification is very useful for analyzing evolutionary relationships and for guiding studies of properties such as sexuality and genetic recombination within populations, but alternative approaches to classification are often more useful when one considers these fungi as human pathogens. As serious fungal infections are often first recognized when fungi are observed in infected tissues or isolated in culture, it is generally useful to divide the pathogenic fungi into groups that grow in tissues or in culture as yeast-like fungi (sometimes with associated elongated forms known as pseudohyphae), as filamentous fungi (or molds), or as dimorphic fungi (which grow as one morphologic form when they are observed in infected tissues or are cultured at 37 °C and as a completely different morphologic form in the environment or when they are cultured at ambient temperatures). Table 2 divides the major human pathogenic fungi into yeast-like fungi (which include both ascomycetes and basidiomycetes), filamentous fungi or molds (which include ascomycetes and zygomycetes), and dimorphic fungi (all of which are ascomycetes).

Some pathogenic fungi cause disease in people with normal host defenses, whereas others cause disease almost exclusively in people whose defenses against infection are seriously compromised. As the adequacy of an individual patient's host defenses is often known well before the etiology of any specific infection is known, it is also useful to divide the human pathogenic fungi into

Table 1 Phylogeny of the common invasive fungi

Phylum	Subphylum	Class	Order	Genus
Ascomycota	Pezizomycotina	Eurotiomycetes	Onygenales	<i>Blastomyces</i>
				<i>Coccidioides</i>

Table 2 Morphology of the common invasive fungi

	Genus	Usual morphology in tissues
Yeasts	<i>Candida</i>	Budding yeast, pseudohyphae, hyphae
	<i>Cryptococcus</i>	Encapsulated budding yeast
	<i>Exophiala</i> (<i>Wangiella</i>)	Black yeast, pseudohyphae
	<i>Trichosporon</i>	Pleomorphic yeast, pseudohyphae or hyphae
Molds	<i>Aspergillus</i> , <i>Fusarium</i> , <i>Pseudallescheria</i> , <i>Scedosporium</i>	Narrow septate hyphae, branching at 45°
	<i>Rhizopus</i> and other zygomycetes	Wide aseptate hyphae, branching at 90°
Dimorphic fungi	<i>Blastomyces</i>	Yeast with broad-based buds
	<i>Coccidioides</i>	Large endosporeulating spherules
	<i>Histoplasma</i>	Small budding yeast
	<i>Paracoccidioides</i>	Yeast with multiple buds per cell
	<i>Penicillium</i>	Intracellular yeast
	<i>Sporothrix</i>	Elongated budding yeast
Other	<i>Pneumocystis</i>	Trophic forms, and cysts that contain up to 8 internal spores

true pathogens that can infect normal hosts and opportunistic pathogens that tend to infect only seriously compromised hosts (Table 3). It should be noted that most of the fungi listed as true pathogens can also act as opportunists because they tend to cause more extensive and severe disease in people with compromised host defenses.

Host Defenses Against Fungal Infections

Humans are continuously exposed to fungi. The majority of fungi are recognized and inactivated within hours by cellular and noncellular innate defense mechanisms. In addition, an important protective mechanism is provided by physical barriers such as intact skin and healthy mucosa. Many fungal infections occur in individuals with predisposing factors that affect or impair the function of skin, mucosa, or airways. A major predisposing factor for *Candida albicans* bloodstream infections, for example, is the placement of an indwelling catheter that provides the fungus with direct access into the bloodstream and internal organs, bypassing the protection provided by intact skin. Another example of a fungus that can take advantage of interruptions in the skin to invade deeper structures is *Malassezia furfur*, a basidiomycete that can contaminate and then proliferate within lipid-containing parenteral nutrition fluids. Filamentous fungi such as the *Rhizopus* can colonize skin that is interrupted by full-thickness burn injuries or by surgical incision, after which the fungi can invade deeper structures and disseminate widely.

Other factors that disturb the integrity of the intestinal mucosa, such as chemotherapy treatments for hematological or neoplastic malignancies, can also allow *C. albicans* to translocate from the gastrointestinal tract into the blood. Besides the mechanical barrier provided by intact skin, secretions that bathe the mucosal surfaces can also influence susceptibility to infection. A group of soluble peptides, defensins, and histatins, found in mucosal secretions and other tissue fluids, have antimicrobial activities, and play an important role in innate immunity. Most of these peptides exert their antifungal activities by interacting directly with the microbial membrane, destabilizing it and leading to cell death.

Protection against fungal infections is afforded by both innate and adaptive immunity. Cellular innate immunity relies upon professional phagocytic cells (tissue macrophages/monocytes and dendritic cells) that are able to ingest and kill certain fungal

Table 3 Pathogenic potential of the common invasive fungi

True pathogens	<i>Blastomyces</i>
	<i>Coccidioides</i>
	<i>Histoplasma</i>

	<i>Penicillium</i>
	<i>Pneumocystis</i>
	<i>Pseudallescheria</i> and <i>Scedosporium</i>
	<i>Rhizopus</i> and other zygomycetes

spores or yeasts, and have an important role in containing fungal growth and dissemination. Another aspect of this first line of defense is the recognition of conserved molecular patterns found on the surface or as part of microorganisms that signal infection to the host. These conserved molecular structures are known as pathogen-associated molecular patterns (PAMPs) that are usually units of cell wall or cell membrane structural components found in large groups of pathogenic microorganisms. PAMPs are 'seen' by host cells through a set of surface proteins called Toll-like receptors (TLRs) and by other membrane-bound proteins (such as Dectin-1, the receptor for 1,3- β -glucan) found on professional and nonprofessional phagocytic cells. Binding of PAMPs by TLRs and other non-TLR proteins signals the recruitment and activation of neutrophils to the site of infection in a manner that is tailored for the killing or containment of a particular pathogen. Recruitment and activation of neutrophils occur by signaling cascades generated by the secretion of chemokines and cytokines by macrophages to produce a beneficial inflammatory response. Inappropriate inflammatory responses have been implicated in allergic types of reactions that do not offer protection against the offending organism.

Adaptive immune responses are also important for protection against fungal infections. This can occur through a cell-mediated mechanism involving T lymphocytes that become activated by binding fungal antigens processed by macrophages, dendritic and other antigen-presenting cells. Dendritic cells are capable of bridging innate and adaptive immunity pathways by virtue of having some TLRs on their surfaces and being able to process fungal antigens to present to T cells in lymphoid tissues. The T cell implicated in cellular immunity to fungal infections is the CD4⁺ helper T cell. CD4⁺ T cells dictate the immune response by managing the activity of other lymphocytes. These T cells are biased (Th1 or Th2) to secrete specific cytokines that produce a protective type of inflammatory response or a maladaptive response that may lead to chronic infections or uncontrolled allergic responses. How these cells are programmed to produce an effective immune response is not entirely clear and is a topic of significant research interest.

Antibodies are also involved in immunity to fungi although their protective role is not as well defined as in the case of cell-mediated adaptive immunity. Most adults and children have naturally occurring antibodies to *C. albicans*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Pneumocystis jirovecii*. Interestingly, populations at risk for *Cryptococcus* infections often have impaired B cell or immunoglobulin repertoires. Animal models have established a role for antibodies in the protection against certain fungal infections, implying that antibodies may also have important roles in fighting these infections in man. Several fungal antigens have been used experimentally to establish their usefulness as vaccines.

The host can also defend itself against microbial invasion by sequestering essential nutrients such as iron. Although this metabolic defense mechanism has been studied in more detail in bacteria, there is good evidence that patients with iron overload syndromes caused either by underlying metabolic diseases or by frequent blood transfusion are unusually susceptible to infection by zygomycetes such as *Rhizopus*. In fact, there have been outbreaks of life-threatening or fatal zygomycosis infections among iron-overloaded patients who have received the microbial iron-chelating siderophore desferrioxamine in an effort to reduce heavy metal levels in tissues. Whereas iron sequestered in mammalian tissues by proteins such as transferrin and lactoferrin is not usable by *Rhizopus*, iron chelated to desferrioxamine is readily usable by these fungi. Thus, these outbreaks highlight the importance of nutrient sequestration as a host defense against at least some fungi.

It should be clear from the discussion above that host defenses against fungal pathogen are complex and incompletely understood. Nevertheless, it is generally true that particular opportunistic fungi tend to take advantage of particular host defense abnormalities. Thus, Table 4 summarizes the fungi that tend to take advantage of interruptions in the skin or mucosal barriers, abnormalities in or deficient numbers of phagocytic cells, abnormalities in cell-mediated immunity, and inadequate iron sequestration.

The recognition of fungi by the innate immune system utilizes fungal molecules that are similar or are shared across species. Many fungi share characteristics such as cell wall composition or their ability to change their morphology in response to temperature, but not all fungi are able to cause disease. This implies that individual characteristics that give some fungi but not others enhanced infectivity exist. As discussed further, even closely related species are not equally pathogenic. How closely related fungi differ at the genomic level has been used to determine what characteristics are important for causing disease. Molecular tools to analyze genomes, inactivate genes, and introduce heterologous genes have tremendously advanced our knowledge of fungal

Table 4 Association of selected pathogenic fungi with host defense abnormalities

Diabetes/acidosis/iron overload	<i>Rhizopus</i> and other zygomycetes

cellular processes and how these can influence infection of the human host. The section below discusses current molecular approaches to better understand fungal biology and how this information has helped us study how fungi cause disease.

Molecular Approaches for Studying Fungal Pathogenesis

The sequencing of multiple fungal genomes has significantly advanced the study of comparative genomics. Cellular processes that are common or unique among species can reveal information about shared structural and metabolic components, and individual characteristics that help a particular fungus evade the immune system or actively participate in the establishment of infection. Not only do genome sequences allow for the comparison of paralogous and orthologous proteins, cross-species genetic information allows for the comparison of the linear order of genes (or synteny), information that may yield clues as to how genetic information has been maintained or lost in different fungi. Newer high-throughput DNA sequencing technologies, called next-generation sequencing (or next-gen), are capable of producing more accurate and complete data sets of whole genomes at a much faster and cheaper rate relative to a few years ago. These advances have prompted the sequencing of many fungi and of multiple isolates of a given fungal species, sometimes revealing that two isolates may differ in genome size. One of the advantages of next-gen sequencing is the ability to determine the whole genome sequence data of fungi recovered from clinical samples. This is especially important for microorganisms that are considered 'unculturable' in the laboratory such as *Pneumocystis jirovecii*. The genomes of opportunistic fungi appear to differ widely in size and in complexity as seen by the number of chromosomes, genome lengths, and abundance of introns (Table 5). Although genome sequencing has revealed invaluable information, the data have yielded few obvious pan-fungal clues as to why relatively few fungi out of thousands tend to cause most of the systemic infections. This is also true of fungi of the same genus: one or two species tend to cause disease whereas the remaining dozen or more are rarely isolated from patients (*Aspergillus fumigatus* and *C. neoformans* being examples). One shared characteristic is the ability to grow well at the host temperature

Table 5 Genome organization of selected fungal pathogens

Classification by morphology	Organism	Genome size (Mb) ^a	Introns?	Number of chromosomes	Ploidy	Mating
Yeasts	<i>Candida albicans</i>	14.3	Few (8% of genes)	8	Diploid	Has <i>MTLa/α</i> ^b loci; mating documented <i>in vitro</i>
	<i>C. glabrata</i>	12.3	Very few	11	Haploid	Has <i>MTLa/α</i> loci; no mating <i>in vitro</i> ; mating unknown

of 37 °C. How this and other growth attributes coded in the genome affect infectivity and virulence is the subject of much interest, and the ready availability of genome sequencing and molecular tools are important resources for furthering such studies.

Next-gen sequencing technologies have also been used to sequence the entire repertoire of RNA molecules expressed in a cell (or transcriptome). This technology or RNA-sequencing (RNA-seq) is capable of cataloging and quantifying any and all RNA species in a given cell. RNA-seq has virtually replaced microarray chips as a way to study gene expression of cells subjected to different stressors or during given growth stages or morphologies. RNA-seq has revealed regions of the *C. albicans* genome (and in the genomes many other eukaryotes) previously thought to be transcriptionally silent to express non-translated RNAs. An exciting and promising use of RNA-seq will be the dual analysis fungus and host transcriptomes. The latter experiment may provide clues as to how both organisms remodel their transcriptomes in response to each other and help researchers understand the biological processes of infection. A limiting factor thus far has been the handling and analysis of the vast amount of data that is generated from these experiments. In spite of this bioinformatics hurdle, the ability to quickly determine, assemble and examine entire genomes and transcriptomes of fungi is revolutionizing how we approach the study of fungal infections.

Comparative genomics has been helpful in many areas such as for the elucidation of signaling pathways, in the discovery of candidate genes involved in host survival or in virulence traits, for the identification of cell surface proteins perhaps associated with host adhesion, for uncovering mating gene loci, and, in general, for establishing genetic relatedness among fungi. An area of heightened interest has been the demonstration of mating in fungi that appear to exist as asexual organisms. Genetic diversity, as provided by mating, is thought as necessary for maintaining species robustness and fitness. Population genetic studies sometimes suggest that sexual reproduction does occur in fungi in the absence of laboratory demonstration of mating. Genomics has been instrumental in uncovering mating loci by homology searches of fungal genomes. Such has been the case for *A. fumigatus* whose genome harbors loci with good homology to *MAT* genes and was subsequently documented to undergo mating in the laboratory, although it appears to propagate in a clonal fashion in nature. In *C. albicans*, the discovery of *MAT*-type-like loci (*MTL*) has led to the description of a parasexual modality of mating that does not produce haploid progeny. Instead, the tetraploid (4n) progeny undergo a concerted chromosome loss to return to the diploid state. The very low recovery of *MTL* homozygous clinical strains (a/a or α/α) appears to diminish the importance of mating in infectivity of the human host, and the description of five major distinct genetically similar groups (clades) suggests that *C. albicans* tends to propagate clonally and mating may be a rare event. In *C. neoformans*, mating type has been associated with virulence as α strains are more virulent than a strains in certain genetic backgrounds. It has long been observed that the α -mating type predominates in clinical and environmental samples, perhaps due to monokaryotic fruiting (a form of sexual reproduction by same mating-type strains) that has been mostly observed in α strains. Whether and how often 'successful' occurs and how this affects pathogenesis or tissue tropism in medically important fungi is unknown. As more genome sequences are completed and analyzed, together with empiric genetic data, similarities may begin to emerge that point toward characteristics that make certain fungi more apt to infect humans.

An invaluable molecular tool for the study of gene function in association with pathogenesis has been the ability to introduce DNA (transformation) into fungi and to specifically target the disruption of genes of interest (Table 6). Transformation systems can be divided into two steps: (1) DNA delivery into the fungus, and (2) integration of the gene disruption DNA cassette into the

Table 6 Molecular genetic tools used to study selected pathogenic fungi

chromosome by homologous recombination, preferably at a rate that exceeds the inherent mutational rate. A gene disruption cassette consists of a DNA fragment with homologous DNA of your chosen gene flanking a selectable marker gene. This gene disruption DNA cassette is introduced into the fungal cell by one of various methods, after which homologous recombination at the chromosomal gene locus results in the replacement of the functional gene with a nonfunctional one carried on the disruption DNA fragment. Once a gene knockout strain is identified by molecular methods, it can be used to determine how the loss of function of the gene of interest affects virulence attributes. Many of the selectable marker genes in use restore a nutritional requirement (e.g., *URA3* for uracil or *ADE2* for adenine), which requires the use of a mutated strain that lacks the functional corresponding marker gene. A disadvantage of this methodology is the inability to create gene knockouts in clinical strains that normally are not mutated in your chosen gene marker. To overcome this problem, several dominant selectable markers such as genes coding for antimicrobials (e.g., hygromycin B resistance) have been engineered for use in transformation systems of several fungi. This obviates the need of an auxotrophic strain for performing genetic studies and also allows for the transformation of clinical strains. A very useful modification has been the development of gene disruption cassettes that are recycled such that one can generate multiple gene disruptions within one strain using the same selectable marker gene.

The ability to specifically target the disruption of genes to study their function has also undergone a methodology revolution in the last few years. A method that utilizes a bacterial enzyme called Cas9 is combined with short 'guide' RNA molecules to target the modification of DNA in the genome. This method termed CRISPR/Cas system for clustered regularly interspaced palindromic repeats/Cas9, has been very successful in generating gene deletions or other modifications (e.g. insertion of DNA sequences at specific sites within the genome) in genetically intractable systems such as in mammalian cells. The two major advantages of this system are the lack of selectable marker genes and the use of short homologous RNA molecules circumventing the often-laborious need to clone DNA disruption cassettes. The CRISPR/Cas system is still in early stages of use and optimization but promises to be an important innovation once applied to pathogenic fungi. The current methods to disrupt or modify genes in fungi are cumbersome thus ways that obviate the use of selectable markers or multiple rounds of transformations will make the generation of mutants faster and easier.

Common Fungal Diseases

In the following section, the characteristics of several of the most important fungal pathogens of humans are summarized, along with information about the epidemiology, clinical and pathologic manifestations, diagnosis, and treatment of the infections that these fungi cause.

Diseases Caused by True Pathogens

Blastomycosis

Causative organism

The causative agent of blastomycosis is *B dermatitidis*, the asexual form of the ascomycete *Ajellomyces dermatitidis*. *B. dermatitidis* is dimorphic in that it grows as a mold and produces conidia in the environment and in culture at $\leq 30^{\circ}\text{C}$ (Figure 1(a)), whereas it grows as yeast-like cells in infected mammalian tissues and when cultured at 37°C . The yeast cells have thick walls; they are multinucleate and reproduce by budding from a broad base (Figure 1(b)). This fungus grows well in media rich in organic content and therefore it is assumed that they subsist in soil, perhaps in decaying wood or near bodies of water. The exact ecology of *B. dermatitidis* is not well understood because this fungus has only rarely been isolated from soil.

B. dermatitidis exists in two mating types (+ and -), both of which are pathogenic. Mating type + and - strains are found in approximately equal proportions in infected people.
